Sexual Jealousy in Long-Term Relationships

Alexandra E. Phillips and Joseph A. Camilleri
Westfield State University, Westfield, MA, USA

Definition

An emotional state that occurs in response to a perceived or real threat to one's intimate relationship from sexual infidelity.

Sexual Jealousy in Long-Term Relationships

Jealousy can be defined as an emotional response to a threat to one's valued relationship, which motivates actions that reduce the threat. Sexual jealousy is a specific form of jealousy in intimate relationships when there is a perceived threat of sexual infidelity and is different from *emotional jealousy*, which is when there is a perceived or real threat that a partner is emotionally involved with someone else (see *emotional jealousy* entry).

Generally, men are more prone to responding to sexual infidelity, whereas women are more prone to responding to emotional infidelity (Sagarin et al. 2012). For men in long-term relationships, sexual jealousy may be adaptive because it functions by alerting them to cuckoldry risk (i.e., probability of unknowingly raising unrelated offspring), motivating them to reduce this risk (Daly et al. 1982). Women's concealed ovulation meant that men can never be entirely certain about their paternity and may therefore unknowingly invest significant time and resources on a rival's child. Cuckoldry, therefore, likely posed a significant cost to men's reproductive success. Such a strong selection pressure suggests traits evolved to identify and reduce such a risk. Cuckoldry risk does not apply to women because mothers are always 100% certain their child is genetically related to them.

Evidence supporting sexual jealousy as an evolved response includes associations between

infidelity risk and various mate retention tactics and violence (Goetz et al. 2005; Daly et al. 1982) to prevent or punish infidelity (Wilson et al. 1995). Risk of infidelity is also associated with semen displacement and sexual coercion, suggesting these tactics reduce cuckoldry risk by engaging in sperm competition if infidelity already occurred (Goetz and Shackelford 2006; Camilleri and Quinsey 2009). Jealous actions, including those that limit the autonomy of one's partner (e.g., trying to limit her contact with family, friends, or other men), seem to target younger (i.e., more reproductively valuable) women, probably because these women are at an age that elicits stronger competition from potential suitors (Buss and Shackelford 1997).

Jealousy may not always accurately indicate infidelity. Judgments about partner infidelity may be incorrect in one of two ways: Believing a partner is having sexual relations with another person when they are not is known as a type I error, or a false positive, whereas believing a partner is not having sexual relations with another when they are is known as a type II error, or a false negative. Haselton and Buss (2000) suggested we can understand these errors as *adaptive errors*, where it is possible that a bias toward making one type of error may have evolved because it is less costly or more beneficial than making the other error. In the case of jealousy, it may be more costly for men to assume their partner is faithful when they are not and less costly to assume a partner may not be faithful when they are. Some data support this hypothesis. Goetz and Causey (2009) found that men are more prone to making mistakes in overestimating the likelihood their partner is unfaithful.

Although jealousy may be adaptive because it motivates mate retention and sexual coercion, there may be unintended by-products of these actions. For example, Daly and Wilson (1998) suggested that coercive responses to perceived infidelity may sometimes be so severe that it results in uxoricide. Even though coercion may be adaptive to prevent infidelity, killing a spouse under such a scenario would not have been adaptive because losing a mating partner and familial retribution is costly. Thus, even though uxoricide

is linked to sexual jealousy, it does not mean uxoricide is an adaptive response to jealousy. Jealousy may also be disordered among some individuals, leading to delusional beliefs about partner infidelity (see *Jealousy: Psychiatric Diagnoses* entry).

Though women are not immune to sexual jealousy, there is evidence to suggest they tend to show greater distress to emotional infidelity because of the potential loss of their partner's commitment and resources (Buss and Haselton 2005; Buss et al. 1992; see *Emotional Jealousy* entry). A barrier to women's fitness is mate quality, which includes having a mate who shares resources to assist with raising and protecting offspring. Women whose partners pursue emotional relationships with other women face reproductive costs due to reductions in parental investment (Sagarin et al. 2012). Thus, women are more susceptible to emotional jealousy because it alerts them to a costly scenario.

The costs of infidelity are particularly salient for individuals in long-term relationships: men risk larger losses from long-term investment in a rival's offspring, whereas women risk larger losses of resources that are redirected to rivals over time. Unfortunately, empirical research on infidelity and sexual jealousy across the life span are not well-established – much of the developmental research on sexual jealousy is cross-sectional rather than longitudinal (see *Jealousy: Developmental Trajectory* entry). From the limited research, it appears as though as people age, sex differences in jealousy still exist, but the magnitude of the effect decreases (Shackelford et al. 2004). This reduced effect is consistent with the notion that risks associated with infidelity decrease with age.

Various studies have confirmed sex differences in jealousy. For example, men find it more difficult to forgive their partner for sexual infidelities, and women find it more difficult to forgive emotional unfaithfulness (Shackelford et al. 2002). Although not all studies find these patterns, a meta-analysis found an overall pattern where men are more prone to sexual jealousy, whereas women are more prone to emotional jealousy (Sagarin et al. 2012).

To summarize, sexual jealousy in long-term relationships appears to be a functional response because it orients people toward reproductive threats and motivates them to reduce such threats through mate retention, violence, and sexually coercive tactics. Jealousy may not always result in adaptive responses. Uxoricide may be a by-product and pathological jealousy is a disorder. Though sex differences in jealousy are empirically well-established, little longitudinal research has evaluated sexual jealousy in late adulthood.

Sexual Orientation

Adam Safron
Northwestern University, Evanston, IL, USA

Synonyms

[Orientation](#); [Sexual preference](#)

Definition

Sexual orientations are enduring patterns of sexual attraction.

Introduction

Sexual motivation is central to some of our strongest emotions and deepest commitments. Its

influence is so pervasive that many of our actions would be incomprehensible without taking it into account. Although the complexity of human sexuality should not be underestimated, it can be reasonably hypothesized that one of the main reasons people are so motivated by sex is because they experience sexual activities as highly rewarding. From an evolutionary perspective, the motivating nature of sexual experience is best explained as an adaptation for ensuring successful reproduction.

Evolutionarily speaking, one would predict that most women would prefer to have sex with men, and most men would prefer to have sex with women. This is precisely what is observed: although a significant number of individuals also report bisexual and homosexual attractions and orientations, most individuals report primarily heterosexual orientations (Bailey et al. 2016). Indeed, the sex of the person that one tends to desire is one of the largest factors differentiating men and women (Lippa 2009).

The term orientation is sometimes used to indicate individuals' self-defined sexual identities. Here, *sexual orientation* will be defined as an *enduring pattern of sexual attraction*. *Sexual preferences*, in contrast, can be thought of as *motivations for particular types of sexual experiences*, regardless of whether or not these motivations are driven by sexual attraction and irrespective of duration or stability. Although sexual preferences are frequently motivated by orientations and identities, preferred sexual expression can also result from a combination of factors that may have little to do with sexual desire.

Nature and/or Nurture

Among attempts to explain the origins of sexual orientations, a major difference between models is the degree to which they emphasize innate and learned factors. An extreme innateness perspective would argue that humans and other animals are genetically programmed to be attracted to features of the opposite sex. In contrast, an extreme learning perspective would argue that all humans are born with a general capacity for

sexual experience, but they are then shaped to have different patterns of attraction and aversion on the basis of their different social roles and personal histories. Debate continues regarding the ways and extent to which nature and nurture shape human sexuality.

To the extent that sexuality is influenced by evolution, adaptations are thought to depend on the relative “feminizing” and “masculinizing” effects of sex hormones on the developing brain (LeVay 2010; Savic et al. 2010). Hormones are believed to be necessary mediators for shaping nervous systems to respond in particular ways toward physical and behavioral characteristics typical of male and female organisms. According to this model, non-heterosexual attraction results from these processes of developmental masculinization and feminization proceeding in ways that are sex-atypical.

Although genetic effects on sexual orientation have been observed, among identical twins where at least one sibling reports homosexual preferences, the probability of the other sibling reporting homosexuality has been estimated to be as low as 24% (Bailey et al. 2016). This limited heritability demonstrates that orientation cannot be completely determined by genetic factors. Aspects of developmental programs contributing to sexual orientation may be genetically specified, but the underlying processes could be disrupted by a variety of environmental factors, especially prenatally. One notable example is the “older brother effect,” wherein each successive older brother increases the odds of the development of homosexuality in men (but not in women), which has been suggested to result from the maternal immune system developing increasingly strong reactions to Y-chromosome proteins found in male fetuses (Bogaert et al. 2017). This kind of model demonstrates how there can be influences on sexuality that are innately determined without being genetically specified.

Alternatively, the intensely pleasurable nature of sexual activity implies that reward learning can have profound impacts on sexuality. Indeed, some have argued that classical and operant conditioning may be a primary means by which adult sexual preferences are established in humans as well as

other species (Hoffmann 2017; Pfaus et al. 2012). The centrality of reward learning has also been suggested by Toates’ Incentive Motivation Model of sexual behavior (Toates 2009).

These proposals are generally dismissed on the grounds that reproduction is central to evolutionary fitness, and so natural selection must have produced specific and robust mechanisms for ensuring adaptive behavior. However, even for behaviors as fundamental to survival as drinking or eating, experience is required for newborn rats to learn the association between approaching water and obtaining hydration when thirsty, or between approaching food and obtaining nutrition when hungry (Changizi et al. 2002). Further, experience-focused models may become increasingly plausible as domain-general learning processes are discovered to be more powerful than previously recognized (Hassabis et al. 2017). Theoretically, evolutionary fitness may have been maximized most effectively by allowing organisms to utilize complex world models learned through experience.

Correlations between differences in sexual orientation and sexually dimorphic brain structures (and their functioning) have been influential in suggesting the importance of innate factors (LeVay 2010). Yet, these neurological differences remain poorly understood, particularly the means by which they impact behavior. Genetically and hormonally differentiated neural systems may indirectly influence what developing organisms learn as they interact with their environments. However, these differences could also result from the brain’s ability to plastically change itself through experience, rather than being caused by organizational effects of sex hormones.

The fact that male sexual orientation is extremely difficult to change is perhaps the strongest objection to the idea that experience may play an appreciable role in shaping outcomes (Bailey et al. 2016). However, this challenge could be addressed by considering sensitive periods of development, as well as the greater plasticity of young brains, which are still in a period of dynamic alteration due to factors such as changing hormones, progressive myelination, and ongoing neuronal and synaptic pruning (Kuhn et al. 2010).

Indeed, sexual orientation could be entirely learned and still be immutable in adulthood. Of course, it is clearly not the case that sexual orientation lacks innate contributions. However, the precise contributions from nature and nurture (as well as their interactions) remain unclear.

Homosexuality: An Evolutionary Enigma

While exclusive homosexuality is rare in the animal kingdom (Sommer and Vasey 2006), prevalence in humans has been estimated to range between approximately 1–5%, with similar rates observed cross-culturally (Bailey et al. 2016). Homosexuality has been shown to have appreciable heritability, with genetic bases suggested by correlates such as gender-nonconformity emerging early in development. Why would such genes persist in the population if they sometimes result in attraction to partners with which reproduction is impossible?

Several solutions to this enigma have been proposed whereby genes contributing to non-heterosexuality may have enhanced evolutionary (inclusive) fitness (Bailey et al. 2016; Sommer and Vasey 2006). One proposal involves increased altruism toward reproducing family members sharing those genes. Or, within a sexually antagonistic selection model, genes for gender atypicality (including in attraction) could enhance the gender typicality and fitness of opposite sex family members. Both of these hypotheses receive some support from studies of cultures where gender atypicality is constructed in terms of a “third sex,” which might have been the most common manifestation of male androphilia over the course of evolutionary history. Alternatively, it may have been the case that genes contributing to homosexual attraction may have increased fitness in other ways when present in some combinations, akin to heterozygote vigor. It has also been suggested that same-sex attraction could have enhanced fitness by furthering alliances, akin to a kind of social grooming. All of these dynamics could have contributed to selection to varying degrees over the course of evolutionary history, and at the present time there is currently

insufficient evidence to know which were most important.

Male proto-homosexuality genes may have been more likely to persist if it were the case that most men had limited reproductive success, potentially reducing the power of stabilizing selection for highly specific sexual preferences. That is, if expected fitness is low by default, there would have been reduced opportunity costs associated with attempting the alternative strategies described above. However, this account would be less applicable to female proto-homosexuality genes, since ancestral women might have been more likely to achieve at least moderate reproductive success, as would be predicted if female choice is the primary bottleneck for mating (Buss and Schmitt 1993).

Bisexuality and Evolutionary Strategies in Women and Men

Genes for same-sex attraction may have been far less deleterious if they were more likely to contribute to bisexual (as opposed to exclusively homosexual) attraction. Indeed, it should be remembered that degree of homosexual or heterosexual attraction is not all-or-nothing, that same-sex sexual behavior is quite common among heterosexually identified people, and that non-exclusive same-sex attraction is much more common than exclusive same-sex attraction (Bailey et al. 2016).

While men appear to have slightly higher rates of exclusive heterosexuality and homosexuality, women appear to be more likely to identify as bisexual, and are much more likely to identify as “mostly heterosexual” (Savin-Williams and Vrangalova 2013). In contrast to men, women often show nonspecific responses to male and female erotic stimuli in terms of genital arousal, attention, and even neural reward system responses (Safron et al. 2017b). Further, women’s sexuality appears to be characterized by sensitivity to social context, or “erotic plasticity” (Baumeister 2000), as well as capacity for change over time, or “sexual fluidity” (Diamond 2016). Indeed, it has even been (controversially) argued

that sexual orientation is best conceptualized as an evolutionary adaptation in which stable sexual arousal patterns are capable of consistently driving behavior over time, and that this mechanism may be present in most men, but not most women (Bailey 2009). Some limited support for this suggestion can be obtained in the finding that paraphilias (i.e., atypical sexual orientations) are more common in men than women.

This potential difference in male and female orienting is also supported by comparative studies of nonhuman mammals (Goy and Goldfoot 1975), wherein bisexual behavior is usually observed in either males or females of a species, but not both. Theoretically, if males could be reliably expected to approach females for mating, then it would have been less important for females to have exclusive orientations, and possibly even beneficial (e.g., in promoting alliances).

Speculatively, less directed sexual orientations in women could have been adaptive in affording greater inclusion of more complexly determined factors in mate choice, such as social status or tendencies toward parental investment. In some cases, a strongly directed arousal pattern could even represent an evolutionary liability for women, considering the potential difficulty of raising a child without male parental investment (Buss and Schmitt 1993). However, there were likely multiple evolutionarily stable strategies among ancestral women and men. It should also be noted that male sexuality might exhibit more plasticity and fluidity than previously assumed (Diamond 2016).

Proximate Mechanisms of Orienting: An Evolutionary-Developmental Enigma

What are the mechanistic bases for sexual orientation? In a seminal investigation of postmortem brains (LeVay 2010), the third interstitial nucleus of the anterior hypothalamus (INAH 3) was approximately twice as large in heterosexual men than in heterosexual women and homosexual men. This particular structure was examined because of its homology with the sexually dimorphic preoptic area, which has been established to

underlie the control of mating behaviors in numerous species (Roselli and Stormshak 2009).

Subsequent investigations partially replicated the gender differences in INAH 3, but only found a nonsignificant trend for smaller volumes in homosexual men, with no differences in neuron number. Perhaps most compellingly, female-typical characteristics of preoptic hypothalamic nuclei have been found to correlate with male rams preferring to exclusively mount other male rams. While these studies appear to constitute converging lines of evidence, it is important to keep in mind both the heterogeneity of these phenomena (e.g., a male rodent exhibiting lordosis is quite different from a male ram that mounts other males), as well as the need for replication with larger samples. Disclaimers notwithstanding, this kind of evidence suggests that a substantial part of sexual orientation might be related to hypothalamic nuclei.

But what is it that the hypothalamus is supposed to be doing with respect to orientation? The most straightforward assumption is that hypothalamic nuclei first detect sexually dimorphic stimulus features and then generate sexual behaviors and motivation. However, determinations of sexual significance are probably made upstream to the hypothalamus in structures such as cortex and the amygdala (Maras and Petrulis 2010; Terzoian and Ore 1955), in which case hypothalamic nuclei would not constitute a direct basis for sexual orienting. While the generation of sex-specific mating behaviors such as mounting or back arching would influence the likelihood of sexual interaction with other males or females, on their own this would not constitute a “hard-wired” sexual orientation, perhaps especially in species with greater degrees of freedom and complexity in available responses.

It is intuitive to assume that most of sexual orientation has its origins in innate responses to visual stimuli. Some of this intuition may be warranted. If nervous systems inherently try to minimize prediction error (Friston 2010), then the enhanced predictability of symmetrical structures and smooth textures could potentially act as primary “rewards” in terms of producing less sensory uncertainty. Yet, definitive evidence has not

been found that mammals are capable of having inborn responses to complex geometric features. However, ambiguous evidence is plentiful, as well as commonly (albeit mistakenly) cited as constituting strong evidence.

There has been a clear primary basis for sexual orientation in vertebrates for hundreds of millions of years: detection of the pheromonal signatures of conspecifics by the accessory olfactory system (Zhang and Webb 2003). However, the claim that humans are responsive to pheromones is challenged by the deterioration of the accessory olfactory system into vestigiality that began with the evolution Old World primates. This system is usually responsible for sensing phylogenetically relevant classes of olfactory compounds from other organisms, and then triggering species-specific fixed action patterns through connections to structures such as the medial amygdala and then the hypothalamus and brainstem. Although primates have shown phylogenetically relevant affective reactions to such odorants (Snowdon et al. 2011), these responses could have been learned, and the vestigiality of the accessory olfactory system further suggests that it may be misleading to refer to these compounds as “pheromones,” *per se*.

Some indirect support for the importance of the accessory olfactory system for innate heterosexual orienting is suggested by reports of frequent bisexual and nonreproductive sexual behaviors in apes and dolphins. These large-brained species lack functioning vomeronasal systems, and their dynamically constructed social niches may have benefited from action selection being driven by more complex (and learned) cortical representations. Indeed, the greater sophistication of cortical controllers may be a primary reason that the vomeronasal organ became vestigial.

However, even in species without functioning vomeronasal systems, smell is a unique sense in several respects. First, compared with other stimulus modalities, smell is more likely to be capable of influencing phylogenetically significant behaviors due to closer proximity of olfactory inputs to core structures for emotion selection, neurophysiological regulation, and memory encoding. Although these areas receive extensive projections from

other sensory modalities, these connections are achieved through pathways with a far greater number of intervening synapses through a dynamically self-organizing cortex. Second, a large number of genes specifically code for odor receptors, which are sensitive to specific compounds. Although only ~400 of our 1000 odor-receptor specific genes remain functional – compared with ~1100 functional olfactory genes in mice – the number of permutations of gene-expression profiles is still enormous. Thus, it is not unreasonable to suggest that evolution was able to use the primary olfactory system to adaptively shape behavior in human and nonhuman animals. Theoretically, if the relationship between the degree of smell-induced arousal and reward is characterized by an “inverted U” function – that is, too weak being unnoticeable, and too strong being aversive – then increasing or decreasing the sensitivities of the innate olfactory system could have provided an elegant means for evolution to cause different smells to have different affective associations. Yet the extent to which this is the case remains unclear.

Potential bidirectional conditioning between olfactory and nonolfactory stimuli suggests that caution is appropriate in interpreting studies of responses to sexually dimorphic smells. For instance, studies using androgen and estrogen related olfactory compounds have demonstrated both differential activations in heterosexual women and men, as well as sex-atypical activations in homosexual women and men (Savic et al. 2010). These studies were invariably reported as suggesting innate bases for preferences. But this sort of inference cannot be made from non-longitudinal observations of adults shaped by a lifetime of experiences with sexual partners.

For example, male marmoset monkeys exhibit increases in serum testosterone in response to sexual odors (Snowdon et al. 2011), potentially suggesting pheromone-like properties. However, after sexual cues were paired with an arbitrarily chosen lemon odor, these novel olfactory associations were capable of stimulating erections, as well as increased exploration of locations where males previously experienced a receptive female. This study demonstrates that learned olfactory associations could potentially produce pheromone-like

effects without relying on specific receptor mechanisms.

To the extent that there are innate biases toward sexual stimuli, the amygdala complex is probably the most likely supporting mechanism in most vertebrates. This system receives extensive olfactory inputs, has been implicated in emotional learning and responses for appetitive and aversive stimuli, and has been shown to regulate sexual behaviors in a variety of animals. Although the amygdala receives multi-modal inputs, complex visual stimuli are unlikely to produce specific innate responses via cortex, given the dependencies of cortical development on idiosyncratic experiences of individual organisms. Theoretically, the superior colliculus could provide this input using connections that are simpler and more predictable than a cortical pathway. However, although this structure receives substantial projections from the retina, receptive field properties of collicular neurons are not sensitive to shape or color (Redgrave et al. 2008), and thus it is unlikely that specific connections from this structure could form the basis for an innate visual stimulus detector.

There are likely many means by which organisms could be innately biased towards sex-specific stimulus features across multiple modalities. For all of these biases, it is important to distinguish between increased salience and specific valence. Attentional biases are likely relatively more simply implemented and evolvable, relative to adaptations for specifically valenced responses. However, if valence can be discovered from experience, then salience biases may be sufficient for ensuring adaptive behavior. Along these lines, if organisms with particular appearances have greater fitness in the evolutionary sense, they may also have greater fitness in the everyday functional sense, and as such it may be unnecessary (and possibly not evolvable) to instill a specific valenced bias for those visual features. For example, if individuals with pronounced sexually dimorphic stimulus features have stronger immune systems, then aversion to sickness could be sufficient for reliably learning the attractiveness of these features (as honest indicators of fitness). Or, if individuals with pronounced sexual

dimorphism are more robust in other ways, then their inherent salience could be sufficient for increasing their ability to generate arousal and possibly desire. In these ways, features such as anatomical symmetry or sexually dimorphic physiology can be nearly universal without necessarily involving innate biases.

Experiments of Nature: Against Nurture?

Ethical considerations preclude an experimental approach in attempting to assess causation in the development of sexual orientations. However, it may be possible to approximate such data by studying “experiments of nature” in which relevant variables have been altered due to chance (Bailey et al. 2016).

In distinguishing between the roles of genes and hormones, androgen insensitivity syndrome (AIS) provides a scenario in which a genetic male has feminized hormonal conditions. AIS demonstrates that the direct effects of male genes on development are insufficient for determining orientation, suggesting the importance of either hormones or experience.

Another class of quasi-experiments involves infantile gender reassignment. The male→female experiment is approximated by male cloacal exstrophy or penile ablation during circumcision, followed by attempted female socialization. The female→male experiment is approximated by congenital adrenal hyperplasia (CAH) in females. Both of these classes of experiments are associated with increased homosexual preference and transsexual identity, showing that (a) sex atypical hormonal conditions at the very least contribute to sex atypical preferences and identities, and (b) genital morphology and attempted gendering are not sufficient conditions for determining orientation.

Outcomes associated with penile removal and CAH provide a strong challenge to learning perspectives on orientation development. Yet for these various scenarios, it is questionable whether someone with constructed genitalia and frequent medical procedures during childhood would relate to their gender and sexuality in exactly the

same way as a natal male or female. Also, these cases all suffer from the confound of overall masculinity or femininity also being sex atypical, which could go on to influence social interactions, which could potentially mediate atypical development of sexual identities and orientations. That is, theoretically, being highly gender-atypical could potentially impact the development of one's sexual orientation.

More broadly, present evidence is insufficient to disambiguate which causal pathways contribute to associations between sex-atypical sexual attraction and other sex-atypical characteristics (Fig. 1). These associations could arise from common origins in shared processes of hormonally mediated neurodevelopment, where sexual differentiation may be disrupted across multiple mechanisms. Alternatively, neurohormonal factors could increase the probability of developing gender-atypical characteristics more generally, through which the probability of sex atypical orientations could also increase. Both of these scenarios may apply to different degrees, depending on the particular contexts that shape particular individuals.

Another class of quasi-experiments involves childhood sexual experiences. The case of self-directed sexual encounters is of limited use due to confounds between preexisting and experience-dependent interest. A better test is provided by non-self-directed sexual activity. The most compelling evidence along these lines may be found in the New Guinea highlands (Baldwin and Baldwin 1989), where all young adolescent males were traditionally encouraged to engage in homosexual activity as a kind of masculinizing initiation ritual. Yet, the vast majority of these men went on to develop heterosexual orientations. While this suggests that childhood homosexual experience is not sufficient for instilling homosexual orientations, it should be kept in mind that these rituals took place in the context of otherwise strong pressures for heteronormative conformity. An additional potentially relevant detail is that this homosexual activity initially happened in a context where the boys mostly performed oral sex, without self-stimulation or explicit eroticization. Theoretically, this sort of noneroticized sexual experience could even lead to habituation or de-valuation. Although these boys also later took on different

Two models of the development of sex-atypical characteristics and sexual orientation

Fig. 1 (A) Standard models assume that sex-atypicality in orientations (i.e., homosexuality) and more general sex-atypical characteristics (e.g. gender non-conformity) both result from a common process of sex-atypical neurodevelopment. (B) However, the same evidence is also consistent with a model in which the relationship

between sex-atypical neurodevelopment and sexual orientations is mediated by sex-atypical characteristics and environmental interactions. Note: An experience-dependent causal pathway should not be taken to imply that sexual orientations are arbitrarily malleable, perhaps especially as plasticity decreases as development proceeds in time

roles where they received sexual pleasure, this only happened in late adolescence. Finally, strong gender-segregation could potentially contribute toward heterosexual preferences based on the (highly contested) proposal that finding male or female conspecifics be erotic may be preceded by finding something to be exotic, and then reattributing that arousal (LeVay 2010).

Further quasi-experimental evidence regarding contributions to orientation development may be provided in coming decades by increased acceptance of nonheterosexuality, as well as increased exposure to different forms of erotica during childhood and adolescence. If experience matters, then prevalence of nonheterosexuality may increase over time and may have already started to change. However, this test is also confounded since it may merely be the case that people are more likely to self-report nonheterosexual preferences and identities if they are less concerned about social rejection.

The Development of Sexual Preferences in Nonhuman Animals

The most powerful experiments for assessing the roles of nature and nurture involve studies of nonhuman animals. This literature suggests that numerous aspects of mating behavior can be shaped by experience, with initially nonsexual stimuli acquiring sexual incentive value (Pfaus et al. 2012). Examples of sexual conditioning range from rats with “fetishes” for the velcro-jackets they wore during early sexual experiences, to rats that desire the smell of the initially unconditionally aversive odor of cadaverine. Sexual imprinting has been observed in numerous species, as in the examples of adult male mice and geese both mating preferentially with females that have attributes similar to those of the females that nursed them early in life. An even more extreme example can be found in inter-species partner preferences resulting from the cross fostering of goats and sheep.

Some potential counter-evidence for the impact of experience can be found in the

observation that while homosexual preferences can be conditioned in male rats, this requires the administration of dopamine agonists (Pfaus et al. 2012). However, the fact that dopaminergic agents facilitate the development of homosexual preferences is not actually an argument against the importance of reward-learning, but rather, may instead suggest that sexuality should be understood similarly to other kinds of motivations, all of which depend upon dopaminergic functioning across countless species.

Brains appear to utilize common general-purpose systems for action selection and reinforcement learning, regardless of the types of value being pursued. This is evolutionarily sensible, since in order to prioritize and decide among heterogeneous alternatives to produce adaptive behavior, organisms must be able to weight and trade off among various kinds of incentives, integrating them into a “common neural currency” of value. The dopamine-sensitive ventral striatum is a particularly important structure for these reward functions in the vertebrate brain, including with respect to sexual rewards (Safron et al. 2017a). Perhaps unsurprisingly, neuroimaging studies have found ventral striatum activation patterns in response to male and female sexual stimuli to be a strong predictor of orientation in men.

Some of the most compelling developmental data of sexual behavior involves male rhesus macaque monkeys, which initially mount other males and females in equal proportions as juveniles, but switch to exclusively heterosexual mounting after puberty (Wallen 2001). Intromissions with other males do occur, but they are more likely to ejaculate with females. Notably, these heterosexual ejaculations are the strongest predictor of the timing of the transition to predominantly heterosexually biased mountings. Although not definitive, these data suggest that copulatory experience is a potentially sufficient mediator for heterosexually directed mating behavior to develop. At least in rhesus macaques, it appears that evolutionary pressures for successful reproduction could potentially be subserved by general-purpose reward-learning mechanisms. Theoretically, the innate basis of orientation may

be found in the body-plan itself – and resulting interactions that it affords – rather than being “hard-wired” in the brain.

However, to the extent that animals engage in social learning, they need not rely on direct experience to discover what behaviors are likely to be rewarding. Rather, animals can partially depend on the fact that evolution may also occur on the level of group behavioral dynamics, with pervasive and enduring selective pressures potentially resulting in aspects of homeostasis extending into culture. With respect to sexual reproduction, cultural evolution might favor groups with norms supporting heterosexual interaction. In this way, evolutionarily adaptive behavior need not depend on complex innate factors, many of which may be expected to become vestigial if selective pressures are reliably satisfied by other means (e.g., whether through rewarding experiences or social learning).

Conclusion

Orientation and Universal Darwinism

Sexual orientation remains an evolutionary and developmental mystery. We do not know the specific ways that innate and learned factors combine to shape orienting. In order to make scientific progress, it will be necessary to obtain a deeper sense of the underlying causal processes in terms of mechanism, development, and phylogeny. Toward this end, a model is proposed for describing orienting on all three of these levels, with the intention of illustrating their fundamental similarity (Figs. 2, 3, and 4).

In generalized evolution, outcomes result from processes wherein the characteristics of systems and their environmental niches cause some interactions to be more likely than others, which then cause differential selective pressures to shape dynamics. When these selected dynamics

Fig. 2 Mechanistically, orienting emerges from a process of sensation being assessed for affective value, so resulting in differential selection of neurophysiological dynamics (e.g., patterns of neural activity, autonomic and neuroendocrine changes). These affective assessments contribute to the selection of global organismic modes, which in turn bias perception in a circular process of

affective construction (i.e., emotions/feelings). The sum total of this dynamic processing shapes overall neuronal activity selection, which may contribute to orienting sexual behavior, so influencing likely future experiences. However, incentive motivation of sufficient strength to influence actions will only be likely to occur if sufficiently robust orienting is present

Developmental causes of orienting

Fig. 3 Developmentally, orientations emerge from a process of ontogenic programs shaping plastic phenotypes and likely affective experiences, so resulting in differential learning (i.e., selection of neural connections). These affective experiences contribute to the shaping of different preferences, which in turn bias future likely experiences in a circular process of niche construction for individuals (i.e., the ways in which organisms both adapt themselves to

their environments and adapt their environments to themselves). The sum total of this experience-dependent affective learning shapes overall preferences, which may result in enduring orientations, so influencing the overall unfolding of a life history. However, preferences of sufficient strength and robustness to be considered to be orientations may only develop if sufficiently robust reward learning occurs during sensitive periods of development

influence the processes that give rise to them, this circular causality constitutes niche construction. Sometimes these feedback cycles cause qualitative differences in system-environment characteristics and resultant selective pressures, surpassing thresholds of organization for the creation of new attractor networks, such that emergent patterns become self-sustaining, potentially increasing their temporal stability. When these emergent processes are allowed to operate over extended periods of time, they influence the overall trajectory of systems and their environmental contexts. This process of selection and feedback is called evolution, and it can be used as a general framework for characterizing all dynamical systems at all levels of analysis. It appears to be the only process in the universe that allows order to be created and entropy to be (locally) resisted.

The similarity of various orienting dynamics is to be expected on account of each level of analysis being constituted by sui generis evolutionary systems (Edelman 1987), operating and interacting on various spatiotemporal scales. That is, to the degree that differential selection among varying patterns can be observed, that is the degree to which a system can be characterized as evolutionary. This includes the differential persistence of neuronal ensembles, emergent behaviors, or types of organisms. Further, each of these evolutionary processes are mutually nested on different timescales, with present moment proximate orienting resulting from historical developmental and phylogenetic causes, which in turn determines future developmental and phylogenetic trajectories. In this way, the principles governing orientations (sexual or otherwise) are shown to reflect, emerge from, and shape the overall evolution of the tree of life.

Fig. 4 Phylogenetically, changes in population characteristics emerge from a process of members of a population interacting with each other and the broader environment, so resulting in differential survival and reproduction (i.e., natural and sexual selection). The consequences of these interactions define operative selective pressures, which in turn bias the conditions of selection in a circular process of population-level niche construction. The sum total of these

pressures shapes the overall direction of selection, which may result in appreciable fitness consequences for different phenotypes, so influencing future population characteristics over phylogenetic history. However, selection of sufficient strength and robustness to produce appreciable fitness consequences (sometimes yielding novel adaptations) may only develop if sufficiently robust selective pressures are present for multiple generations

Sexual Orientation and Human Sexuality

Jaroslava Varella Valentova and Marco Antonio Correa Varella

Department of Experimental Psychology, Institute of Psychology, University of São Paulo, Cidade Universitária São Paulo, SP, Brazil

Synonyms

Bisexuality; Heterosexuality; Homosexuality; Same-sex sexuality; Sexual attraction; Sexual minorities; Sexual preference

Definition

Sexual orientation refers to a psychological mechanism directing one's sexuality towards

individuals based on their apparent sex. Individuals form a continuum between extreme point of exclusive heterosexuals, i.e., oriented exclusively towards individuals of the opposite sex, and exclusive homosexuals, i.e., oriented exclusively towards individuals of the same sex, with bisexuals being similarly attracted to both sexes and other individuals being attracted to both sexes in various degrees (e.g., predominantly heterosexual with some potential to same-sex attraction). Sexual orientation refers more to attraction or desire than behavior or identity, because orientation is not necessarily manifested by overt sexual behavior, associated with self-identification of sexual orientation label, or aligned with affectional bonding (love).

Introduction

The majority of males and females predominantly prefer opposite-sex sexual and/or romantic partners. Such sexuality has been accepted as a standard default, possibly because it is easier to see its biological/evolutionary relevance. Indeed, in sexually reproducing species, preference for and sexual activities with opposite-sex partners evolved as a mechanism for combining genomes through complementary gametes gaining genetic variability and direct fitness. Thus, scholars have argued that homosexuality is an evolutionary puzzle because it impedes the reproductive success of their owners. However, on the phylogenetic level, evolutionary fitness is more than direct fitness, and on the ontogenetic level, sexuality is more than fertile heterosexual penile-vaginal intercourse. Although direct reproduction is the ultimate evolutionary force behind most sexual activities, sexuality in general gained many other proximate functions during its evolution, e.g., as a social and pair bonding mechanism or means of resource acquisition. Such functions are intermediate goals to achieve direct reproduction, e.g., by means of survival and alliance formation and/or indirect reproduction by helping kin, also known as inclusive fitness. Therefore, many forms of sexuality, such as oral or anal sex, masturbation, sexual preferences for different species,

preferences of same-sex individuals, or individuals outside of reproductive age, cannot *per se* offer direct reproductive success of the individual, but still these nonfertile forms of sexuality can offer other adaptive sociosexual functions (e.g., pair bonding, alliance formation, resource acquisition, well-being, etc.) that might indirectly foster future reproduction, regardless of sexual orientation. It is important to note that personal motivations for sexual activities, homosexual or heterosexual ones, are quite different from their possible sociosexual functions or possible evolutionary adaptive values. Sexual relations are mostly motivated by pleasure, love, self-esteem/revenge, and/or obtaining resources. Such personal motivations triggering homo/heterosexual behavior should not be confused with the socioecological or evolutionary reasons that maintain sexual activity in the population.

Further, sexual orientation is a psychological mechanism that generates a continuous array of individual variation and not a dichotomous psychological trait (e.g., Kinsey et al. 1948; Petterson et al. 2015). In this sense, exclusive homosexuality and exclusive heterosexuality present the extreme opposite poles of the continuum, while the majority of individuals fall in between, although closer to the heterosexual extreme. Following this line, homosexuality or non-heterosexuality (including bisexuals) is more than exclusive homosexuality, and sexual orientation does not equal homosexuality. One possibility would be to focus on the adaptive value of the mechanism itself (i.e., sexual orientation); the other would be to explore the possible adaptive value of one of its manifestations (e.g., exclusive homosexuality). The adaptiveness of the mechanism itself is usually not the focus of the debate. The debate is mostly centered on whether and how the individual differences generated by this mechanism are adaptive. A mistake would be to extrapolate a possible nonadaptiveness of an extreme point within the continuum (exclusive homosexuality) to the other variations along the whole continuum of sexual orientation (e.g., predominantly heterosexual, bisexual, predominantly homosexual, etc.). Similarly, a severe clinical depression or severe forms of autism are

most probably not adaptive; they are not only neutral but rather maladaptive. However, they both are extremes on a continuum of adaptive variation, such as the capacity of sadness and systemizing abilities, respectively (for an overview about adaptive individual differences see, Buss and Greiling 1999). In the same line, bisexuality or some degree of homosexual tendencies among predominantly heterosexual individuals as well as some heterosexual tendencies among predominantly homosexual individuals could be viewed as adaptive variation of sexual orientation. From this perspective, even if exclusive homosexuality does not have any possible adaptive value, it would be a mistake to assume that the same is true for the whole continuum of sexual orientation.

Evolutionary Theories of Sexual Orientation

Sexual orientation has been described as a mechanism navigating or directing sexuality towards individuals of the opposite sex, same sex, or in varying degrees to both sexes (Bailey 2009; Bailey et al. 2016; Savin-Williams 2016; Vrangalova and Savin-Williams 2012). Similar to some heterosexual practices (e.g., extra-pair affairs), attitudes toward same-sex sexuality can vary greatly between cultures. In some cultures, same-sex sexuality constitutes an integral part of the sociocultural system; in others such sexuality is criminalized and persecuted (for review see, Bailey et al. 2016). For these reasons, individuals can vary in their overt manifestation of sexual preference, from a tendency hidden from public or even self to open preferences and behaviors. There are also other motives why sexual preferences, behaviors, and identities do not need to be aligned. Nonpreferred sexual behavior can be manifested, for example, under conditions without access to preferred sexual partners; it can be done for financial motives or simply to satisfy one's partner. Similarly, romantic affection can be largely disconnected from sexual desires (Diamond 2003). For example, a person can repeatedly fall in love only with individuals of the same sex, but prefer

and actively seek sexual partners of both sexes. Thus, sexual orientation refers to sexual desires, attraction, and preferences rather than to overt sexual behavior, identity, or affective feelings.

Sexual orientation has a genetic component that explains approximately one third of the variation between individuals (e.g., Zietsch et al. 2012; for review, see Bailey et al. 2016). This suggests that sexual orientation is a complex trait that is influenced by genetic and environmental factors. Sex hormones are one of the environmental factors that influence the development of sexual orientation. According to the organizational hypothesis, the neural system of homosexual individuals is influenced by sex-atypical hormone levels during early developmental phases. Systematic differences in neuroanatomy between homosexual and heterosexual individuals suggest that compared to their heterosexual counterparts homosexual men were, on average, less androgenized and homosexual women more androgenized during early, probably prenatal, development (for review, see Bailey et al. 2016; LeVay 2010; Wilson and Rahman 2005). Neither genetic nor hormonal influences suggest that sexual orientation is necessarily fixed and rigid over the lifespan. Sexual orientation develops during ontogeny whereas sexual identity can change over time, particularly among women (Diamond 2008). Such a fluidity of sexual orientation does not equal to a conscious choice of different sexual desires and attractions (Diamond 2008). Thus, sexual orientation is not a choice nor a cultural invention; it has genetic and neurohormonal underpinnings and is not necessarily immutable. Furthermore, occasional same-sex behavior and stable same-sex preferences have been documented along a number of nonhuman animal species (Sommer and Vasey 2006). Thus, a variation on the sexual orientation continuum is not a human specific and has its phylogenetic roots.

Moreover, it is commonly accepted that homosexuals do not have any reproductive success. Although it has been shown that reproductive success of transgendered male homosexuals (males who adopt female look and behavior) is close to zero (Vasey et al. 2014), this does not need to apply to other forms of nonheterosexual

individuals. In one study, 32.8 % of men and 65.4 % of women reported a potential for homosexual response, suggesting that a huge percentage of predominantly heterosexual people do have a propensity to experience same-sex sexual attraction and/or interaction (Santtila et al. 2008). In this study, the potential for homosexual response was based on responses (quite impossible, very unlikely, quite unlikely, not likely, not unlikely, relatively likely, very likely) on the following question: "If a, in your opinion, handsome man [to male participants]/beautiful woman [to female participants], whom you like, suggested sexual interaction with you, how likely would you be able to do it (if you could define the nature of the interaction and nobody else would know about it)?" In line with this finding, a large-scale study demonstrated that almost 10 % of heterosexually identified men reported that they have engaged in same-sex sexual activities (Pathela et al. 2006). This applies even more to non-Western populations, such as Samoa, where the majority of predominantly heterosexual men engage in sex with both women and transgender males called Fa'afafine (Pettersen et al. 2015). Further, 20 % of homosexually identified white American men reported having been married to a woman at some point in their life, and 50 % of homosexual men reported having produced at least one child (Bell and Weinberg 1978). According to the more recent demographic data (2013) of the USA, 37 % of LGBT-identified individuals report having at least one child. Keeping in mind these assumptions, we can outline some of the empirically supported evolutionary theories explaining the adaptiveness of human homosexuality and nonheterosexuality.

1. Homosexuality as an adaptation: Kin selection theory

One of the oldest and partly supported theories of homosexuality as an adaptation was postulated by E. O. Wilson (1978), inspired by Hamilton's kin selection theory. Homosexual individuals, who do not invest into their own exclusive reproduction, may propagate their genes indirectly by supporting reproduction of close relatives, with

whom he/she shares own genes. Studies conducted in the USA, Great Britain, or Japan did not support the theory (for review, see Bailey et al. 2016), which can be explained by persisting relatively negative attitudes toward homosexual individuals in these countries. On the other hand, systematic investigations of Fa'afafine, who are officially recognized as "third gender" or a transgender type of male homosexuals (individuals who are biologically males but have feminine characteristics and adopt feminine gender roles) among the population of Samoa, supported the theory of kin selection. In particular, Fa'afafine show higher avuncular tendencies (support of nieces and nephews) compared to men who prefer women as sexual partners, which supposedly increases their fitness (e.g., Vasey and VanderLaan 2010). Samoan Fa'afafine fit a specific subgroup of homosexual men, the transgender type of male homosexuals that is a specific although still heterogeneous group. This subgroup of transgender individuals whose sexuality is aimed at individuals of the same biological sex is frequent in many other societies, such as India (Hijra), Thailand (Kathoei), or native North American tribes (Berdache). The transgendered homosexuals mostly prefer same-sex relationships, although usually with cisgender (i.e., biological sex aligned with gender role) men. Sexual and/or romantic relations between partners of different gender roles are documented in numerous populations around the world (Crapo 1995). Furthermore, age stratified type of same-sex relationships (i.e., one of the partners is much younger than the other) has been documented across populations, such as ancient Greece, Middle Ages Japan, or contemporary New Guinea (Crapo 1995). Such relationships, as opposed to gender-stratified ones, do not need to imply one transgendered and one cisgender partner, rather both of them are cisgender but of different age categories, although such interactions can be temporary and do not need to imply predominant same-sex preferences of none of the partners. Both age-stratified and gender-stratified styles of same-sex relationships exist in the modern Western culture, although the most frequent style of relationships is egalitarian between two individuals who identify as homosexuals and are of similar gender role, status,

education, and age. This latter style of same-sex relationships seems to be specific for contemporary Western populations. On the other hand, the other two styles of same-sex relationships appear in populations that share more common sociocultural characteristics with human ancestral populations (e.g., geographical connectedness of the kin and strong familiar bonds), and the evolutionary strategy can thus still be adaptive in the present as it could have been advantageous in the ancestral environment (VanderLaan et al. 2014). Importantly, evolutionary strategy of transgender homosexuals can differ from the one adopted by cisgender homosexuals or nonheterosexuals. In other words, some evolutionary hypotheses (e.g., kin selection) can be supported in one specific subgroup of homosexual individuals (e.g., in transgender homosexual men) in specific society contexts (e.g., large families, close kin bonds, geographical proximity) but not in others (e.g., in cisgender homosexual men in big anonymous cities with prevalent homophobia).

2. Homosexuality as a by-product of sex-atypicality

Miller (2000) suggested that male homosexuality per se is not adaptive, but rather it is a by-product of another adaptation. He proposed that some characteristics that are, on average, more typical for women than men, such as lower aggressiveness, higher cooperation, and social skills in general, became adaptive also in men during the changes in social structure of relatively recent human evolution. Further, more feminine characteristics in men can be typical for slow life history of men who invest more in relationship commitment and parental care than in mating success (Jeffery 2015). Thus, men who have more feminine and fewer masculine characteristics can thrive better in a more complex and predominantly monogamous society, including having relatively higher reproductive success. In this scheme, male homosexuality would thus be an extreme nonadaptive by-product of a general adaptive male shift to feminization. Gender non-conformity (lower masculinity in men) has a strong genetic component (for review, see Bailey

et al. 2016), and women find femininity in men attractive (Perrett et al. 1998). Furthermore, numerous studies indicate that nonheterosexual men are, in comparison to heterosexuals, more feminine (for review, see Bailey et al. 2016). Homosexual men would thus form an extreme point on a continuum between male masculinity and male femininity, while relatively feminine heterosexual men would have some adaptive advantages, at least in urban, middle class Western groups. In line with the kin selection theory outlined above, this theory also aims to explain the existence and maintenance of feminine male homosexuals in the population. This theory, nonetheless, does not apply to masculine male homosexuals and other nonheterosexuals nor to female homosexuals. Rice et al. (2013) suggested that homosexual orientation is a by-product of sex-atypical epigenetic marks that feminize males and masculinize females during embryonic development. Thus, the opposite logic of the theory could also be applied to explain masculine female homosexuals who would represent an extreme pole of a general female masculinization. This might have been adaptive for some women during the evolutionary past, for example, by concentrating more social and physical power, leading to higher independence, better self-defense and defense of their kin, and higher resource acquisition. Such characteristics might have been advantageous in the ancestral and also recent society, where mortality in men has been relatively higher than in women.

3. Predominant homosexuality as an adaptation: Sneaking and conditional sexual strategy

Following the previous line of reasoning, predominant homosexuality in feminine males can be also understood as a sneaking sexual strategy (Jeffery 2015). In humans, it has been suggested that the most frequent strategy would be exclusive or at least predominant heterosexuality with males of rather masculine characteristics, while bisexuality and predominant homosexuality linked to increased femininity in men would represent a sneaking sexual strategy. From this point of view, feminine men who have some potential for

opposite-sex activities can be successful in opportunistic heterosexual activities and secure direct reproductive success. This can happen in particular because feminine characteristics were shown to be attractive to women (e.g., Perrett et al. 1998), at least under certain conditions. At the same time, more feminine bisexual or predominantly homosexual men can be perceived as weak rivals to more masculine exclusively or predominantly heterosexual men and can thus reduce intrasexual male-male competition. Consequently, feminine predominantly homosexual men can be accepted more as friends of heterosexual men's female partners, thus offering opportunities to sneak copulations. High numbers of predominantly homosexual individuals reporting some opposite-sex attraction, behavior, and also biological offspring (see above) would tend to support this theory. The theory thus does not attempt to explain exclusive homosexuality or transgender homosexual men who do not have any interest in sexual encounters with opposite-sex partners. It rather shows that various degrees of bisexuality and predominant homosexuality can serve as an alternative and successful reproductive strategy. This theory need not apply only to men because bisexual and predominantly homosexual women can also show some opposite-sex attraction and behavior, as well as some reproductive success. On average, lesbian women are more masculine than heterosexual women (Bailey and Zucker 1995), and masculine heterosexual women report higher sociosexuality (tendency for uncommitted sexual variety) than feminine women (Mikach and Bailey 1999). We can thus speculate that masculine predominantly homosexual women can secure direct reproductive success without the necessity of creating and maintaining long-term bonds with men but rather with other women. Compared to predominant female homosexuality or bisexuality, a fluid sexual orientation might have helped ancestral women secure resources and care for their offspring under conditions without a primary male partner by receiving parental investment from other women (Kuhle and Radtke 2013). According to this theory, fluidity of female sexual orientation can be understood as a conditional sexual strategy, meaning that variations between opposite-sex and same-sex sexuality can be

adaptive in different conditions, such as different age or life phases.

4. Nonheterosexuality as an adaptation: Same-sex alliance formation

This theory holds that various degrees of sexual feelings and behaviors aimed toward both males and females offer an individual advantage over an exclusive orientation toward only one sex (Kirkpatrick 2000). The main reason towards non-heterosexual interactions would be formation and maintenance of same-sex alliances that are crucial in many other primates and in particular in the human evolutionary past. The author shows anthropological and primatological evidence supporting the view that strong and emotional same-sex alliances can offer a reproductive advantage to the individual. More specifically, same-sex alliances reduce competition and increase cooperation between members of the same sex, while maintained access to partners of the opposite sex ensures potential reproductive success. In this perspective, heterosexual sex among stable partners outside the fertile period (i.e., outside the fertile window within the female menstrual cycle and after menopause) or any sexual activities that do not lead to fertilization (e.g., oral or anal sex) serve the same function, i.e., reducing disputes, increasing cooperation, and thus maintaining the stable dyad (Bártová and Valentová 2012). The question is whether non-heterosexual behavior was originally selected for alliance formation or whether alliance formation is rather a newly acquired sociosexual function of same-sex sexual behavior. In this sense, non-heterosexuality would serve proximate sociosexual functions for which nonprocreative sexuality in general was co-opted, such as alliance formation, dyad maintenance, lowering stress, peacemaking and reconciliation, or resource gains.

5. Homosexuality as a by-product: Overdominance and sexually antagonistic gene hypothesis

Both behavioral and molecular genetic studies have shown that the male homosexuality is linked, among others, to the X chromosome and is thus inherited from the maternal lineage

(Sanders et al. 2014). Further, female relatives of male homosexuals have more children and grandchildren than control group of women with no homosexual individuals among relatives (e.g., Ciani and Pellizzari 2012; for review, see Bailey et al. 2016). It is thus suggested that greater fecundity and fertility of female relatives of homosexual men can explain the persistence of a nonadaptive form of male sexuality through sexually antagonistic selection (e.g., Ciani and Pellizzari 2012; Zietsch et al. 2008). In other words, sexually antagonistic genes can bring advantages for one sex (e.g., higher fecundity in women) but can be principally disadvantageous for the other sex (e.g., can cause exclusive homosexuality in men). However, as shown by recent models, the frequency of only female carriers cannot explain a stable proportion of exclusive male homosexuals in the population but a large proportion of both nonhomosexual female and male carriers can (Chaladze 2016). Based on behavioral genetic studies, a considerable proportion of men carrying the homosexual genes are not exclusively or predominantly homosexual. It was suggested that homosexual phenotype can only be expressed in a homozygous form of the underlying alleles, while individuals with a heterozygous form (only one allele of the gene) carry the phenotype but the phenotype is not expressed (for review, see McKnight 1997). Such heterozygous carriers are supposed to possess some advantageous characteristics that can increase reproductive success of their owners. So far, this theory was supported by a study showing that heterosexual twins of homosexual men, who most probably share the genetic component of homosexuality although not homosexual orientation, report higher number of female sexual partners than heterosexual men with a heterosexual twin (Zietsch et al. 2008). Thus, heterosexual men who carry the homosexuality-linked genetic component, potentially in a heterozygous form, do have higher mating success (considered a proxy of a reproductive success) than the control group of heterosexual men, which can explain its relatively stable prevalence in the population.

The theories of by-product thus focus more on explanation of the extreme exclusive form of male homosexuality, rather than the rest of the

nonheterosexual continuum. The theories can apply to other forms of nonheterosexuals, though, because they can also be carriers of the homosexual genotype. It has been shown that a potential for homosexual response has a stronger genetic component than homosexual behavior or self-labeled identification (Santtila et al. 2008). Thus, any degree of nonheterosexual tendencies might be more suitable for genetic analyses than exclusive homosexuality with no heterosexual potential.

Furthermore, the theories of homosexuality as a by-product originally did not apply to women, although in principle they can work similarly, since genetic component has been documented also in female sexual orientation (for review, see Bailey et al. 2016), and the potential to homosexual response is even more frequent in women than men (Santtila et al. 2008). Thus, exclusive male and female homosexuality indeed can be a by-product of otherwise adaptive variation of sexual orientation.

Conclusion

During the last century, human and other animal (vertebrates and invertebrates) sexual orientation has been extensively studied within many scientific areas. Despite important findings in the areas of psychology, anthropology, medicine, neuroscience, genetics, endocrinology, and development, evolutionary reasoning has suffered numerous conceptual and terminology issues. These misconceptions have led to the view that homosexuality can only be exclusive and thus an evolutionary paradox. However, when essentialist categorical thinking is discarded, it might become clearer that the majority of variation on the continuum of sexual orientation can offer adaptive advantages for their carriers. This view can be supported by changing the perspective of sexuality equaling only with reproduction, and by acknowledging the fact that at least some homosexual and nonheterosexual individuals within the whole spectrum of sexual orientation do reproduce and raise their offspring.

Most outlined theories present adaptive reasons for the evolution of nonheterosexual orientations, either by stressing indirect reproduction via kin selection or direct reproduction via sneak

populations or same-sex alliance formation that can increase survival and future direct reproductive capacity. Even by-product theories offer plausible evolutionary reasoning for the origins and maintenance of nonheterosexual orientations. In this sense, nonheterosexual orientations would have been passed on throughout generations together with the adaptive trait of sex-atypicality, advantages of an increased fertility in the other-sex kin, or in carriers who do not express the homosexual phenotype. These theories are not mutually exclusive, and together they can explain a bigger proportion of the sexual orientation continuum. Moreover, these theories offer a stronger case against the argument that it is impossible for any form of homosexuality to have evolved.

Finally, it is important to realize that the outlined theories are not *just-so-stories* nor naïve panadaptationism as critics often portray it. The theories offer specific hypotheses with predictions that can be empirically tested. We attempted to provide the existing empirical support for each theory, although we realize that more research using a variety of sources of evidence and methods is still needed. Only convergent evidence of numerous empirical tests can give decisive support and scientific credibility to a particular adaptive hypothesis.

Sexual orientation is a complex psychological mechanism that can profit from analysis within an evolutionary framework, where otherwise heterosexuality might be taken for granted. Future studies should pay more attention to female nonheterosexuality, to sex-typical nonheterosexuals, bisexuals, integration and empirical confrontation of the existing theories, and to empirical testing of the theories in Western as well as non-Western populations with varying concepts of same-sex sexuality.

Definition

Sexual outcomes caused by different life history strategies refer to biological outcomes such as timing of puberty or sexual maturation and behavioral outcomes such as effort in mating, frequency of sex, number of sex partners, and risky sexual behaviors.

Introduction

Sexual outcomes are among the major manifestations of life history (LH) strategies that lie along the fast–slow continuum. Organisms with fast LH

strategies sexually mature and reproduce early, have high numbers of offspring with small body size, and invest more energy and effort in mating than in parenting, whereas organisms with slow LH strategies exhibit the opposite pattern of sexual outcomes. In evolution, human beings have generally adopted slow LH strategies, as compared to other animals. However, individual differences in LH among human beings are observable because people grow up under different ecological conditions and ambient environments, which triggers different LH strategies (Belsky et al. 2012). Specific sexual outcomes caused by LH include biological outcomes, such as the timing of puberty and sexual maturation, and behavioral outcomes such as sex debut, frequency of sex, number of sexual partners, mating effort, conservative versus unrestricted sociosexual orientation, and risky sexual behaviors.

Known as LH tradeoff strategies, the essence of LH theory is the allocation of finite energy resources among an organism's growth, reproduction, and body maintenance functions (Belsky et al. 2012). Less allocation to body maintenance and growth but more allocation to reproductive functions is characteristic of fast LH strategies, whereas more energy allocation to growth and maintenance over reproduction is characteristic of slow LH strategies. Furthermore, efforts in reproduction include mating associated with offspring quantity and parenting associated with offspring quality. Mating and parenting represent energy tradeoffs in that more energy investment in mating trades quality for quantity of offspring in fast LH strategists, whereas slow LH strategists trade quantity for quality by investing more in parenting than mating. Timing of puberty is a transition of energy allocation from physical growth to reproduction, and subsequent mating behaviors reveal energy allocation among mating, maintenance, and parenting.

Biological Outcomes

In harsh but stable environments where resources are scarce, individuals adopt slow LH strategies whereby they allocate a large proportion of limited bioenergy to physical development and body maintenance rather than reproduction and thus

exhibit late puberty. For example, insufficient nutrition delays the age of menarche (Soliman et al. 2014). Improvements in nutrition provision from the 1920s to 1980s have lowered the mean menarcheal age from 13.3 to 12.4 years among American girls (McDowell et al. 2007). In Western European and Scandinavian countries, menarcheal age declined from approximately 17–18 years in the mid-nineteenth century to the present population means of 12 or 13 years. In recent decades, the age of menarche in China and Japan has declined by 3.5 months for every 10 years, which is also consistent with data from Copenhagen showing a 3-month decline in menarcheal age from 1991 to 2008 (Soliman et al. 2014). Furthermore, insufficient nutrition results in smaller sexual organs. After puberty, adolescents who were born with a low birth weight because of insufficient fetal nutrition showed small testicular volumes for boys and small internal genitalia for girls (Soliman et al. 2014). In addition to resource scarcity, high intraspecies competition for limited resources also triggers slow LH strategies, which are characterized by high parenting and skill training of the young so that they become able competitors to monopolize the limited resources (Ellis et al. 2009). The bioenergy of children is thus allocated to building the body and skills more than to reproductive readiness.

In unpredictable and harsh environments resulting from warfare or pandemics on the macroenvironmental level or familial dysfunction or unstable parent–child relationships on the microenvironmental level, individuals adopt fast LH strategies to reproduce as fast and as early as possible before extrinsic mortality and morbidity strike (Ellis et al. 2009). An obvious example is menarche in girls, whose reproductive life lies in the interval between menarche and menopause. Although early menarche results in a longer reproductive tenure than menarche at the normative age does, early menarche does not necessarily lead to high fecundity throughout the lifespan because of the elevated risk of miscarriage and long protogenetic intervals. The major benefit of early menarche is the increased chance of early reproduction prior to potential unexpected mortality.

For example, paternal absence and consequential harsh maternal parenting (Belsky et al. 2012) are significant cues of early puberty. In evolutionary history, paternal absence indicated insufficient resource provision and a lack of paternal protection from unsafe environments or predators. Thus, paternal absence signaling a harsh and unpredictable environment ahead causes early maturation and reproduction before unpredictable mortality and morbidity strike.

To a lesser extent, biological outcomes that have been observed in men can help distinguish between fast and slow LH strategists. For example, earlier onset of puberty predicted more masculine facial morphology, larger biceps circumference, and higher BMI among young male adults (Doll et al. 2016). These characteristics contribute to reproductive success by improving intra- and intersexual competitiveness as opposed to parental investment. In men but not women, earlier onset of puberty representing fast LH strategies has also been found to predict greater sex drive, interest in casual sex, and reported number of lifetime sex partners (Ostovich and Sabini 2005). Other studies show that men growing up without fathers or with low paternal involvement matured earlier, had sex earlier, and became fathers at younger ages (e.g., Sheppard and Sear 2012).

Behavioral Outcomes

Numerous studies have focused on the behavioral and attitudinal outcomes of fast versus slow LH strategies in allocating energy resources to mating versus development. For example, young adults growing up in an unpredictable environment characterized by parental employment transitions, household relocations, and paternal transitions (e.g., paternal absence) were found to have more sexual partners and be more active with oral sex and sexual intercourse (Belsky et al. 2012). Adults who grew up in a stable environment were found to be more committed to long-term relationships, were more likely to use contraceptive measures to control birth, and showed more restricted attitudes toward sex (Brumbach et al. 2009). In addition, slow LH strategies have been shown to correlate negatively with high effort in mating and short-

term mating orientation, suggesting that individuals with slow LH strategies do not concentrate time and energy on mating or switching sexual partners. Moreover, environments triggering different LH strategies also affect mate selection. In resource-scarce environments where slow LH strategies are likely to be adopted, people prefer long-term partners with characteristics of good parents and resources provisioning capacity. When primed with environmental stability, women prefer good fathers over good genes in selecting long-term partners (Lu et al. 2015). Similarly, women with insecure attachment styles or with unrestricted sociosexuality, both of which represent a fast LH strategy, preferred short-term relationships more than other women and preferred men who pursue a short-term mating strategy (Kruger and Fisher 2008).

Individuals with fast LH strategies show unrestricted patterns of sexual behaviors. In general, they invest more effort in reproduction than in personal development and more effort in mating than in parenting. In unpredictable environments that trigger fast LH strategies, because future survival is uncertain, investment in developing personal skills and competence does not guarantee a return on the investment. In such cases, investment in reproduction rather than future development is more likely to facilitate fitness enhancement or gene continuity. Similarly, survival of offspring is also uncertain in unpredictable, harsh environments such as those affected by warfare or disease. An unexpected bomb explosion may nullify intensive parental efforts invested in few offspring. Adapted strategies are to mate and reproduce as much as possible to hedge against unpredictable mortality, rather than to bet on few high-quality offspring vulnerable to stochastic unpredictability. In neighborhoods with high homicide rates (indicative of environmental unpredictability), women have their first birth earlier than those in more peaceful neighborhoods (Wilson and Daly 1997). Similarly, chronic childhood illness, conflictual family interactions, and paternal absence or underinvolvement have been associated with early reproduction and sexually promiscuous mating strategies, whereas people who grow up in

stable environment and intact families are more likely to delay sexual experience, have positive attitudes toward, and develop stable pair-bonds (Belsky et al. 2012). Longitudinal data also show that slow LH measures taken at 14 years of age were a significant predictor of timing of first sexual act, frequency of sexual activities, number of sexual partners, number of abortions, and likelihood for having contracted venereal disease measured at subsequent ages up to 32 years of age (Dunkel et al. 2015).

Conclusion

LH strategies are manifestations of tradeoffs in bioenergy allocation between development and reproduction. Timing of puberty reveals the tradeoff between physical development and reproduction, and late puberty and small sexual organs are biological sexual outcomes of slow LH individuals who primarily allocate energy to the development of the brain and body. Efforts invested in sexual behaviors reveal the tradeoff between personal or future development and reproduction, and slow LH individuals allocate energy and time in skill development to enhance their personal competitiveness and in parenting in order to improve the adaptiveness of their offspring. Individuals with fast LH, by contrast, exhibit early puberty and emphasize offspring quantity over quality. They invest energy and time in mating with more partners and reproducing more offspring and thus show unrestricted sociosexual orientations and favor good-gene over good-parent characteristics in their sexual partners. The literature and the present review have focused on sexual activities and physiological characteristics related to sexual maturation, both of which are under natural selection. Future research can also examine sexually selected traits (e.g., fluctuating asymmetry, voice pitch, waist-to-hip ratio, as well as culturally acquired traits such as creativity and sense of humor) in relation to the fast-slow LH strategic continuum. Such an approach is particularly relevant to men who are under much stronger sexual selection pressure than women. Because sexually

selected traits that are costly to build and maintain represent investment in reproductive effort, they are subject to the same LH tradeoff in relation to somatic and body maintenance effort. For example, it will be interesting and informative to explore how fast vs. slow LH strategists allocate energetic budget between sexually selected traits and behaviors and those related to growth and development.

Definition

Sexual pathology or disorders of sexual preference refer to persistent and intense sexual interests lasting at least 6 months, where sexual arousal is in response to atypical fantasies, behaviors, objects, situations, or partners. These behaviors, fantasies, or urges can cause distress, interpersonal difficulties, or functional disorders and usually involve non-consenting persons, nonhuman objects, juveniles, or the infliction of humiliation and suffering.

Introduction

At present, the evolutionary approach is a relatively common theoretical framework for describing and interpreting various aspects of human sexuality, such as differences in sexual behavior between sexes or common sexual responses in the general population. This is coherent considering the fact that the main success criteria are from an evolutionary perspective reproductive success – all psychological, physical, and behavioral traits directly linked to reproduction are of primary interest, and the search for adaptations in this area is intuitive. However, the search for the adaptive meaning of sexual deviations (paraphilias, disorders of sexual preference) is more complicated. This text will introduce the evolutionary approach to the study of paraphilias (or, using evolutionary terminology, “sexual variations”). Firstly, a definition of evolutionary sexology as a scientific framework will be given, along with an explanation of the specifics of the evolutionary frame applied to the disorders and variations linked to sexuality, and finally, with the aid of specific examples of paraphilias, an explanation of the ways in which an evolutionary analysis of particular symptoms in currently diagnosed disorders of sexual preference can be achieved will be given.

What Is Evolutionary Sexology?

Evolutionary sexology is a specific area of evolutionary psychiatry, which, to quote R. Nesse (2002), helps one understand why psychiatric syndromes exist at all and why some of them are so common today. It focuses mainly on evolutionarily ultimate sources, (i.e., what given trait was/is adaptive in the history of evolution for and how it brought reproductive success to our ancestors and also to us). According to Bailey (1991), from the evolutionary perspective, sexual paraphilias are phylogenetic regressions, updated repressed mechanisms, which were adaptive in the past. Evolutionary sexology utilizes a few existing indirect evidences of adaptiveness (behavior strategies or cognitive mechanisms):

1. *High population prevalence.* The prevalence of homosexuality, which was until recently seen as a deviation, ranges today between 5% and 6% across the populations (Diamond 1993). Some sexual paraphilias and dysfunctions, which are still psychiatric diagnoses, have a similar degree of prevalence, for example, various fetishes or sadomasochism.
2. *Similar prevalence across different sociocultural environments.* For example, the sexuality incorporating the submissive or afflicted position of one of the partners and the dominating or pain-inflicting position of the other is found in many human cultures and societies across historical periods studied to date.
3. *Existence of complementary (i.e., opposite) paraphilia in potential or realistic partners.* For example, mutually consenting sadistic/masochistic practices.
4. *Occurrence among different species closely connected on the phylogenetic tree.* For example, male and even female sexual behavior focused on sexually immature individuals is commonly found in various animal species, including primates, chimpanzees, and bonobos (Dixson 1998).
5. *Connection between the high prevalence of a specific sexual strategy and a specific environment type that can provide reproductive success.* For example, the accelerated arrival of first menstruation has been found to occur in dangerous, scarcely resourced, low-income environments, coupled with a high birth rate and low parental care. First sexual encounters occur sooner and demonstrably more offspring are produced. In these types of environments, greater mating activity is a valuable countermeasure against a relatively truncated life expectancy. It is interesting to note that it is not only a case of adaptation in behavior but also physiology – a significantly lower age of first menstruation means that the timing of biological reproduction forms part of this complex adaptive sexual strategy (Gangestad and Simpson 2000).

The specifics of evolutionary scope applicable to disorders of sexual preference and variations

can, therefore, be summarized into the following points: (1) independence of determining what is normal from contemporary environment, society, and culture; (2) emphasis on specific symptoms and relative independence from presently valid medical diagnoses; (3) utilizing findings from classical and human ethology and evolutionary psychology; (4) acknowledging the fact that nature and nurture, the innate and taught, put the finishing touches to the final result of human sexuality; and (5) taking into account the phylogenetic history of sexual behavior, variation, or deviations (Klapilová et al. 2016; Stevens and Price 2016).

Determining Sexual Normality and Abnormality Is Independent from Contemporary Environmental, Societal, and Cultural Norms

While a physician may view rarely occurring phenomena as proof of defects and deviations that are to be normalized or treated, the evolutionary approach considers the same phenomena as a part of natural diversity and variation or as a specific sexual strategy that can, under certain conditions, be adaptive and bring some evolutionary advantages (Nesse 2002). According to the classical Euro-American medical sexology, sexual behavior is “normal,” when between consenting, mature, non-related individuals and when it does not incur psychological or physical damage to either partner. When diagnosing sexual preference disorder, specifying what appears in the sexual fantasies of a person is crucial, specifically the object the person presents sexual attraction toward and who he/she desires to form a partnership with. A psychiatric diagnosis is only necessary when the personal orientation causes the individual (or his/her surroundings) excessive psychological difficulties or adverse effects to their quality of life (excessive stress, suicidal tendencies, feelings of shame and/or guilt) or has led to socially unacceptable or illegal behavior (e.g., the search for underage sexual partners). In other words, paraphilias become a psychiatric problem only when society (or the individual) deems them to be so.

It is important to realize that sexuality is not demonstrated only through behavior, meaning how and with whom one has sex. It does not have to reflect internal preference (Laws and O'Donohue 2008). Apparently, only a minority of people with paraphilias realize their preferred sexuality. Likewise, some sexually *normal* individuals can engage in deviant behavior, even though their preference and sexual fantasies fulfill (in their particular society) traditional concepts of sexual objectification and activity. Therefore, the number of individuals in the population with paraphilic tendencies remains unknown. To determine the prevalence of paraphilic preferences across a population, it is necessary to research not only behavioral experience but also thoughts, fantasies, and arousal toward paraphilic material as well as love emotions toward paraphilic objects.

The Swedish representative research focusing directly on paraphilic behavior noted that 3.1% of men confessed at least one exhibitionist and 7.7% at least one voyeuristic incident (Långström and Seto 2006). Studies targeting pedophile preferences state a prevalence from 0.3 to 3.8% (Mohnke et al. 2014). And lastly, the studies aimed at sadomasochistic experience show, in the USA and Australia, a prevalence from 2.2 to 11% (Hite-Corrie 2012). The fairly high percentage of occurrence detected in previously published studies and their comparisons across different nations and cultures indicate that thinking about the adaptiveness of these sexual strategies is worthy of research.

Emphasis of Individual Symptoms and their Relative Independence from Presently Valid Medical Diagnoses

Another advantage of the evolutionary approach is the perception of individual symptoms (which are part of contemporary medical diagnoses) as independent elements that can have, in different contexts, differing developments and adaptive significance. Individual symptoms may have more adaptive functions, and therefore, it is necessary to look at them from different angles as to avoid their misinterpretation. A fitting example would

be that when watching women's physiological reactions under laboratory conditions, women with "normal" sexual preferences (as opposed to paraphilic patients) have been known to react with a significantly more arousal and vaginal lubrication to stimuli showing aggressive sexual activities (Suschinsky and Lalumière 2011). This, however, cannot simply be explained by presuming that most women are sadomasochistic. The evolutionary explanation presents a hypothesis of preparedness, which is an advantage whenever there is an increased chance of forced penetration, lowering the risk of significant genital harm. Lubrication, therefore, functions as an independent body expression, a symptom present in more contexts than simply being reflective of sexual arousal during intercourse with a preferred partner. It also occurs as part of a defense reaction to an expected incident of sexual attack.

The Application of Knowledge from Classical Ethology, Human Ethology, and Evolutionary Psychology

In evolutionary sexology, the application of knowledge from classical ethology, human ethology, and evolutionary psychology is a key. Sexual behavior in humans is derived from a reproductive function. However, throughout human evolution, social groups have gradually grown and gained complexity, and child-rearing has high demands, especially in the acquisition of complicated social abilities. The combination of these factors meant that, during human evolutionary history, sex took on a number of social functions and began to show in different interactive contexts (Thornhill and Gangestad 1996). It is therefore necessary for humans to understand sexuality as more than just a reproductive tool and rather as a collection of adaptations including mate preferences, mate choice, courtship, and finally partnership formation. The ultimate evolutionary function of sex (i.e., reproduction) is not independent of many other adaptive and social functions of sexuality.

Sexuality is not only about sex, but a genital phase, but is also another step forward in establishing a potential partnership or sexual

relationship. From the viewpoint of basic sexology research into disorders of sexual preference and sexual dysfunctions, this forms an important perspective. From the evolutionary view, we can consider them, mainly, as disruptions in partner selection and partnership formation (i.e., courtship disorders) leading to the inability to sexually function within partnerships (Freund 1990). Sexuality can also be looked at as a hierarchal system of ordered motivational states (SMS, sexual motivation system), a superior brain mechanism running the functional structuring of fragmentary phases of sexual interaction, defined by authors as the potential partner location, non-tactile/affiliative interaction, tactile interaction, and genital interaction (Madlafousek et al. 1981). This theory was strongly inspired by ethological knowledge of mammals gained in the 1970s, in which courting was distinguished by three phases: (1) attractiveness (paying attention to an object's sexual stimuli with specific physical signs), (2) proceptivity (viewing signals of male/female interest and the attempts at courtship), and (3) receptivity (viewing signs of a female's preparedness for coitus and exercising sexual intercourse; Beach 1976). Before making the next step in the motivation system, the lower motivation level must be satisfactorily completed (e.g., before proceptivity, attractiveness must be established). A male's sexual reaction must therefore proceed in this order: recognizing the female's attractiveness and her sexual interest and then interacting with her until after genital contact. If any of these parts takes place outside its order or is skipped, sexual excitement will be reduced (Madlafousek et al. 1981). Apart from the prioritization of positive patterns that lead to sexual arousal, every motivational level has a matching adverse pattern that lowers sexual excitement and interrupts the transition to the next phase. The key is therefore emphasizing the processes around the perception and production of nonverbal expressions (both positive/stimulant and negative/inhibit) in different phases of courtship. People with paraphilia are therefore, in some older ethological theories, seen as individuals who differ from the typical population exactly in their interpretation of perceived

interest/disinterest signals and in their inability to conduct adequate courtship expressions at the correct moment (Freund 1990; Money 1986). This is especially the case with paraphilic individuals who reach sexual arousal and satisfaction atypically (voyeurism, exhibitionism, frotteurism, toucherism, and sexual aggression). The sexual aggressor is able, for example, to perform sexual intercourse with a woman (genital phase), only if not subjected to any signs of seduction from her side. Of course, he himself does not conduct courting behavior. He skips the pre-tactile phase straight to the tactile and genital phases and avoids any interactive synchronization with the woman.

Theoretically, unusual sexual preferences can also arise from an effect similar to imprinting (i.e., an instinctive learning mechanism that takes place during critical development periods). According to Aronsson (2011), the internalization of non-adaptive preference mechanisms (e.g., shoes or other fetishes) is analogical to adaptive preference internalization mechanisms (e.g., our parents' characteristics). Likewise, according to the *erotic target location errors* theory, it is possible to define some paraphilic groups (especially fetishism and transvestism) as development errors when determining the sexual (erotic) object. These errors then lead to a sexual preference for an object's sexually unimportant attributes, for example, a focus on a woman's shoes instead of the woman herself (Freund and Blachard 1993). It is not clear, though, why some sexual preferences, such as fetishism or transvestism, occur only in a small part of the population. The objects preferred by these people are also, during particular sensitive periods, subjected to individuals who do not embody this specific sexual preference. It is therefore probable that other factors also play an important role in the development of these preferences.

Nature/Nurture and the Innate/Acquired Together Complete the Final Result of Human Sexuality

To a great extent, innate and universal human-specific traits are particular signs of attractiveness

(in both genders) that signify genetic quality and fertility. There are such signs of attractiveness in which people from all cultures across history, even across age categories, agree on (e.g., face symmetry). Perceiving these universal signs is mainly genetically conditioned (even newborns automatically give them their increased attention), though it calibrates during their lifetime. Some parts of sexual behavior seem to have a strong innate part, e.g., copulatory pelvic thrusts are already present at a young age (Yang et al. 2005). In human behavioral displays, however, it is rarely the case that it would emerge automatically without being activated by an important stimuli, which must come from an environment (or fantasy). Contact with the demanded stimuli is mostly necessary in order to activate the adaptive strategy in a given sensitive period of ontogenetic development. These are seen as relatively long developmental periods in the individual's development when the nervous system is ready to increasingly react to specific stimuli from an environment that activates the occurrence of a given behavior. According to the neurodevelopmental sexual trajectories of Pfaus et al. (2012), there exist a few basic sensitive developmental periods in which the basic form of sexual (and partnership) life is constructed and in which we learn *who* will sexually attract us, *with whom* we will want to form a partnership, and *what activities* will bring us the biggest sexual pleasure.

Our sexuality is gradually shaped in these sensitive periods, starting with the consolidation of strongly innate sexual orientation and gender differentiation by creating preferences to/aversions toward sexual partners similar to the preferences/aversions of the people surrounding us (primary family), all the way to forming strong individual preferences for characteristics of a sexual partner, objects, or favorite sexual activities. This formation mainly takes place through experiences with sexual arousal and reward, meaning pleasurable feelings derived from arousal and orgasmic experience. The chosen behavioral displays continue to be reinforced by positive or negative experience during the following development stages (Pfaus et al. 2012), and according to recent theories and knowledge on brain neuroplasticity, these

displays are fine-tuned throughout their life (Doidge 2007).

This long journey toward an individual's sexual "maturity" suggests huge variability and flexibility in the forming effects of experience and environment. Within the scope of innate variability, individuals differ precisely in this flexibility. Genetic predispositions to various paraphilias evidently determine how much an individual is genetically predisposed to internalize unusual objects into their SMS (e.g., in fetishism). Similarly, genetic components can determine the length of the sensitive period and the degree of SMS rigidity toward transcripts based on later sexual experiences. For one person, a fetish can be the only and necessarily demanded object for inducing sexual excitement, whereas for another, its usage by a partner only increases attractiveness and sexual arousal.

The Importance of the Phylogenetic History of Sexual Behavior, Variation, or Disorder

It is important to take into account the phylogenetic history of behavior, variations, or deviations, which, in practice, means to assess whether the given element appears in other (close and also far related) species and in what frequency. The systems clearly linked to reproduction are very basal and are driven by ancient (in terms of phylogenesis) parts of the brain. The systems related to hierarchies appear in species with growing social groups. The systems and adaptations, which concern the creation of deeper dyadic links, whether between partners or between caregiver (parent) and offspring, are then rather young and inclined to changes in environment and mutations (Stevens and Price 2016). All of these systems use an identical arsenal of neural mechanisms linked to motivation and perception of reward. For example, according to evolutionary psychiatry, sadomasochism has its origins in the linkage of two phylogenetically ancient adaptive systems – reproduction and social hierarchy. They joint to be a part of a specific sexual strategy losing its original function and together provide a

reward in the form of sexual satisfaction. The key events in sensitive childhood periods (e.g., physical punishments or abuse during adolescence) may activate both these systems simultaneously. This association via conditioning consequently strengthens the preferred sexual strategy and begins to produce sadomasochistic fantasies and motivate similarly tuned behavior. It is probable, however, that some people are more genetically predisposed than others for this bonding (Stevens and Price 2016). The results of intercultural studies focused on sadomasochistic practices indirectly support this theory. These practices often have a strongly ritualized form that obviously copies phylogenetically ancient forms of ritualized pain-inflicting behavior already present in lower vertebrates (Stevens and Price 2016). This genetically affected behavior helps establish social hierarchy and sustain differences between dominant and submissive individuals, consisting in signal use designed to increase one individual's status and reduce that of a submissive. The repertoire of signals differs between species, but it is possible to isolate universal patterns in them. Dominance across species is indicated by erecting one's posture and looking at the rival directly, while in contrast, the submissive will crouch and avoid eye contact (Darwin et al. 1998). Escalating signals during hierarchal battles include using physical strength and causing the opponent pain. In terms of human sadomasochistic activities, this sequence is also kept – the dominant figure emphasizes his supremacy through signs of social status, power, or physical size (uniforms, heels), begins a ritual of verbal aggression (degrading comments), threatens and intimidates, and even commits physical punishments and inflicts pain, with gradual intensification (Kamel 1980).

Zillmann and Bryant (1984) describe how the connection between hierarchal and sexual systems can mechanically occur within the framework of the *excitement shift* theory. According to which, the connection is possible because, on the sympathetic nervous system activation level, the activity is not linked to aggression or distinguished by fear and sex, and within the scope of sex play the two systems can *help each other* in escalating physical arousal. It seems that it is not only a case of

hierarchal systems but any emotion from so-called *agonistic systems* to which classical ethology classifies aggression, dominance, and power, as well as submissiveness, fear, and flight. Dominance and submissiveness and aggression and fear are then two sides of the same coin, which, hand in hand, can be used even in the sexual context. The connection between these systems is strengthened, thanks to the secretion of endogenic opiate endorphins, which are released as a reaction to a threatening stimulation (pain, fear), reducing the intensity of physical and mental pain and increasing the feeling of satisfaction. In combination with sexual arousal, it can multiply the submissive's postcoital satisfaction. This theory, though, does not explain why most sadomasochists describe the occurrence of sadomasochistic fantasies unambiguously preceding realistic experiences with these activities. It therefore seems that the described linking can occur beyond being mediated, through imagining psychic pain or causing pain.

Another example can be pedophilia (Seto 2008). For diagnosing pedophilia, constant sexual interest in prepubescent children is pivotal, being expressed for at least 6 months through fantasies, desires, sexual arousal, or behavior and causing the investigated persona distress. The most cogent symptom is falling in love with a child object. As in the case of sadomasochism, the evolutionary explanation behind the origin of pedophilia refers to the fusion of two evolutionarily ancient adaptive systems – reproduction and nurturing. Money (1990) states that a pedophile's relationship to a child qualitatively, and also neurologically, resembles a blend between parental and erotic love. Likewise, it can be linked to the close cohesion between these two systems that can be observed also between phylogenetically close species. For example, baboons create coalitions between young males and sexually immature females, even though the males behave sexually toward them only after they have reached sexual maturity. The founder of the human ethnology field, Irenäus Eibl-Eibesfeldt (1973), directly warns about the type of affiliative-erotic relationship that connects to the composition of long-term partnership, which was developed both in mammals and birds together with nurturing behavior,

and therefore it is not surprising that they are occasionally mixed in humans. This explanation corresponds with the ethological viewpoint; therefore, it is a case of dysfunctional interaction and preference of nonverbal behavior that is typical for children, not of the pedophile's primary preference of a child's bodily figure. It is however unquestionable that treated pedophiles react with penile arousal also when seeing static pictures of child objects.

Conversely, Quinsey and Lalumiere (1995) presume that the emergence of pedophilia is related to the displaced mechanism of sexual preference. According to them, the male sexual preference system is one of complex modules that is often tuned to such characteristics that are important mainly when selecting a partner. These modules are relatively independent from each other and serve to detect the object's gender and his age (youth), body shape (mainly waist-hips ratio), and health. Furthermore, the authors claim that there is a failure of the module detecting and evaluating body shape, which causes the module for distinguishing age to malfunction. This claim is supported also by the fact that in opposition to non-pedophilic men, there is a higher percentage representation of homosexual and bisexual individuals among pedophiles, i.e., individuals who prefer the male figure, whose shape (waist-hips ratio) resembles prepubescent individuals (Quinsey and Lalumiere 1995).

The child's adaptive behavioral function to demand nurture from adults and his prospective urge to perform sexual activities is not mentioned too often. Still, it is a rather widespread behavior across cultures and historical periods that can help the child receive extra resources not available from their own parents. It would therefore be a complementary strategy – from the pedophile's side, there is the eroticization of nurturing behavior and attraction to signalization that encourages caretaking, whereas from the child's side, it is a functional, environmentally conditioned strategy that brings benefits in the form of resources and possibly even acquisition of sexual experience and calibration of child sexuality (Stevens and Price 2016). It is then interesting that such a large percentage of the common population associates behavior of

providing care and signaling need with erotic charge, attaching sexual practices and fantasy scenarios to them (e.g., schoolgirl and teacher).

From an evolutionary perceptive, of course, there are differences between pedophilia and the so-called hebephilia (sexual attraction to pubescent children between 11 and 14) and ephebophilia (sexual attraction to adolescents between 15 and 19, Blanchard et al. 2009). Despite the unacceptable nature of pedophilia, it is necessary to note that pictures of partially developed pubertal naked girls can create arousal in non-pedophilic heterosexual males (Blanchard et al. 2009). From an evolutionary perspective of men's reproductive success, it would be illogical to avoid female objects already able to reproduce, even though the strongest arousal is present with women around 25 years old. The occasional pairing with pubescent girls can therefore fall into the spectrum of normal variability in heterosexual preferences.

Conclusion

The evolutionary approach allows one to look at disorders of sexual preference as adaptive behavioral strategies, which have an innate element. It also suggests that the most important specifically human adaptation is the ability to modify one's sexual preference in relation to their environment, society, and culture. This carries, to an extent, the ability to change the adapted or, in critical periods, taught aspects of sexual scenarios even in later life, even if these changes are within inherited predispositions. The approach facilitates the distinguishing between parts of a sexually motivated system that are rigid to modification (and have a strong inherited component and ancient phylogenetic origin) and parts of a sexually motivated system dependent on environment and experiential influences. An emphasis on ontogenetic development and the concept of genetically programmed sensitive periods allow key factors for the forming of sexuality described in earlier psychology literature of different paradigmatic settings to be taken into account (e.g., repeated formulas of sexual abuse, physical punishments during childhood).

Sexual Prejudice (Personality Correlates of)

Sara E. Burke and John F. Dovidio
Department of Psychology, Yale University, New Haven, CT, USA

Synonyms

[Homophobia](#); [Heterosexism](#); [Homonegativity](#)

Definition

A negative attitude toward individuals or groups on the basis of their sexual orientation.

Introduction

Sexual prejudice involves negative thoughts about, feelings toward, and action orientations toward non-heterosexual people (Herek 2009). Although the word homophobia is sometimes used to refer to sexual prejudice against gay men and lesbian women, it emphasizes a particular affective response – fear – and has fallen out of favor among many researchers due to its presupposition that sexual prejudice stems primarily from fear. Most research on sexual prejudice has focused on negative attitudes toward gay and lesbian people, with some recent attention to bisexual people, but the phrase can also refer to prejudice against other sexual orientation groups (e.g., asexual people). Herek's (1994) Attitudes toward Gay Men and Attitudes toward Lesbians Scales are commonly used measures of individual differences in sexual prejudice.

Bases of Sexual Prejudice

Sexual prejudice is rooted in both intergroup and intragroup psychological processes. With respect to intergroup processes, some heterosexual people view gay, lesbian, and bisexual people as members of one or more different social groups whose existence and actions threaten heterosexual people's values and well-being. In terms of intragroup processes, some heterosexual people may perceive non-heterosexual people as individuals who deviate from norms of sexual behavior in their larger social context and thus are believed to merit negative attitudes and treatment.

Personality and Individual Differences in Sexual Prejudice

Social dominance orientation (Sidanius and Pratto 2011) is one of the most robust individual-difference measures for predicting a range of biases against groups perceived to have low social status. People who are higher in social dominance orientation believe more strongly that group

hierarchies are inevitable and desirable and see the world as involving greater zero-sum competition between groups for resources. Individuals who score higher in social dominance orientation exhibit greater sexual prejudice.

Because some people view non-heterosexual people, either individually or as a group, as deviating from the sexual standards of a society, sexual prejudice often also reflects rejection of perceived norm violators. Many cultures (including the US) have historically valued heterosexual relationships through laws, religious doctrines, and social traditions. Sexual prejudice relates to a range of personality and individual-difference factors associated with negative responses to violations of traditional norms.

Authoritarianism, which is a personality variable that involves a strong motivation to maintain social order and stability, predicts biases against a variety of groups that are perceived as violating social norms, including sexual minorities. The most widely used measure of this construct is the Right-Wing Authoritarianism Scale (Altemeyer 1998). This measure represents a core “attitudinal cluster” that includes authoritarian submission (an inclination to submit to those of greater authority), authoritarian aggression (general hostility toward deviants and outsiders), and conventionalism (a strong commitment to the traditional norms and values of one’s group).

Several demographic variables related to adherence to normative standards also predict sexual prejudice in North America. Because many religious doctrines present same-gender relationships as inconsistent with their values, people who are more religious tend to display greater prejudice against sexual minorities (Whitley 2009). In addition, political conservatism consistently predicts such prejudice. Older age predicts greater sexual prejudice in contemporary studies, perhaps reflecting changing social norms, and higher levels of formal education are related to less sexual prejudice (Herek 2009).

Sexual orientation is intrinsically linked to gender, because it is defined by the experience of sexual or romantic attraction to people of particular gender groups. The norm against same-gender relationships can be viewed, therefore, as a gender norm. Thus, individuals who endorse traditional gender roles

more strongly or are more sexist (e.g., as assessed by the Ambivalent Sexism Inventory; Glick and Fiske 1996) exhibit greater sexual prejudice.

Several demographic factors related to the endorsement of conventional gender norms systematically relate to sexual prejudice. For example, displaying one’s heterosexuality appears to be a vital piece of modern gender norms, especially for men. In part because masculine gender norms are often perceived as less flexible than feminine norms, men’s prejudice against sexual minorities tends to be stronger than women’s. Although men and women differ in their levels of prejudice against other groups as well, strength of gender identification appears to be an especially important predictor of heterosexual men’s sexual prejudice.

Conclusion

Sexual prejudice is rooted in both perceived group status differences and perceived violation of social norms – both intergroup and intragroup processes. As a result, personality and individual differences in factors related both to relations between groups and to social stigmatization within a group predict sexual prejudice. One implication of this observation is that the relative influence of personality factors on sexual prejudice may vary as a function of whether sexual orientation is framed as a set of discrete groups. A second implication is that the dynamics of sexual prejudice may vary for responses to different sexual minority groups. For example, gay men and lesbian women may be more likely to be seen as a discrete group than bisexual people, thus engaging different bases of sexual prejudice. Understanding the personality and individual differences that contribute to these processes is an active area of research.

Sexual Promiscuity

► Sperm Competition: Evidence in Nonhumans

Sexual Receptivity

Danielle Wagstaff
Federation University Australia, Churchill, VIC,
Australia

Synonyms

Sexually accepting, Open to sex

Definition

Acceptance of attempts at, or offers of, sexual intercourse

Introduction

Sexual receptivity refers to an acceptance of sexual intercourse and is contrasted with (although not necessarily distinct from) proceptivity (initiating and/or maintaining sexual intercourse) and attractivity (attracting others to engage in sexual intercourse). Since the male of the species is typically always receptive to female sexual advances, female sexual receptivity imposes a reproductive limitation.

Continuous Sexual Receptivity

Human females possess an extended sexuality, whereby they are receptive to sexual intercourse across both the fertile and non-fertile phases of the menstrual cycle, suggesting human sexuality is solely defined by conception (which can only occur within a brief window of the menstrual cycle, MC). This extended sexuality differs from the majority of the great apes, with the notable exception of the female bonobos, *Pan paniscus*. Although other nonhuman primates show signs of extended sexuality (e.g., wild Assamese macaques, *Macaca assamensis*). This extended sexuality is closely linked with concealed ovulation, that is, lack of external signals of estrus (but see Haselton and Gildersleeve 2011, for a discussion of potential cues to cyclical fertility in humans). Scholarly debate has centered on the evolutionary advantage of this continuous receptivity and whether the adaptation was driven to the benefit of the male or female or instead evolved as a by-product of changes in morphology and physiology. For example, Alexander and Noonan (1979) proposed that extended sexuality increases paternity uncertainty, an advantage for the female who then reaps resource benefits from the male at all times. Alternatively, Thornhill and Gangestad (2015) argue that continuous receptivity evolved as a means enabling cuckoldry of the primary partner, allowing the female to seek good genes elsewhere, in line with strategic pluralism (Gangestad and Simpson 2000). Still other researchers have argued continuous receptivity serves a social-bonding mechanism or facilitates a system of trading sex for reward.

Sex Differences in Sexual Receptivity

Despite women's continuous sexual receptivity, they are not indiscriminate in their acceptance of sexual offers, with sex differences in receptivity readily observable. Clark and Hatfield's (1989) classic experiment demonstrated that women and men who were approached on a college campus by an opposite-sex stranger were equally willing to accept a date from the stranger, but only men were willing to accept an offer to "go to bed." These differences in sexual receptivity reflect evolved sex differences in sexual strategies theory (SST). Specifically, SST argues that both sexes have evolved short-term and long-term sexual strategies, although context will differentially affect the extent to which men and women pursue these strategies (Buss and Schmitt 1993). Because women are the more discerning sex (they are choosier), they are less likely to pursue a short-term sexual strategy than men are.

Hormonal Variation in Sexual Receptivity

Women may show a pattern of sexual receptivity which varies across the MC. Guéguen (2009) demonstrated that women were more likely to accept an offer of sex from a stranger when in the fertile phase of the MC than the non-fertile phases. Other researchers have demonstrated that women engage in more sexual activity when fertile. For example, Harvey (1987) demonstrated fertile phase peaks in both male-initiated and female-initiated sexual intercourse episodes, implying MC effects on both receptivity and proceptivity. Recent advancements in hormonal and MC research and recommendations for how to calculate MC phase (Gangestad et al. 2016), however, limit the reliability of these findings. Specifically, while a large body of research has previously found evidence for the effect of the MC on women's sexuality and sexual strategies, more recent, methodologically rigorous, research contradicts some of these findings. Relatively little recent research has investigated the effects of reproductive hormones or the MC on sexual receptivity in human females. For example, Jones et al. (2018) found only an effect

for general sexual desire, however, did not measure receptivity, specifically.

Cues to Sexual Receptivity

Women may actively signal their sexual receptivity to men. In nonhuman primates, wild female chimpanzees, *Pan troglodytes schweinfurthii*, use copulation calling as a signal of receptivity to high-ranked males. In humans, perceived cues to sexual receptivity may include clothing choice, walking style, and other nonverbal behaviors. One body of research proposes red clothing serves a sexual signal in human females. For example, women wearing red (compared to white) are perceived to be sexually receptive by both men and women. However, recent research has called the association between red clothing and perceived sexual receptivity into question.

Conclusion

Sexual receptivity in human females is a limiting resource in reproduction. Women show continuous sexual receptivity, the evolutionary advantage of which is debatable, and may reflect attempts at facilitating cuckoldry, or serve to increase paternity confusion. Despite continuous receptivity, women show variation in receptivity which is possibly linked with MC. The extent to which women signal sexual receptivity is unclear.

Sexual Regret

Leif Edward Ottesen Kennair and Mons Bendixen
Department of Psychology, NTNU – Norwegian
University of Science and Technology,
Trondheim, Norway

Synonyms

Action regret; Inaction regret; Negative postcoital emotions; Rumination

Definition

Regret is a counterfactual cognitive-emotional response to past events, where one in hindsight wishes the past had been different. Regret comes

in two forms: inaction regret, which is the regret of not having acted when one had the chance and missed out on what proved in hindsight to be an attractive opportunity, and action regret, which is the regret of having done something that in hindsight proved to be less positive than one assumed at the time of acting. Casual sex regret is therefore the specific regret of either having had casual sex or passing up an opportunity for having casual sex.

Introduction

Research on regret finds that sex differences are domain specific. The major sex difference in regret is for romantic relationships and is not present for other domains such as parental relationships, friendships, or academic achievement (Roese et al. 2006). In two studies involving romantic relationship regret, Roese and colleagues found that men reported markedly more inaction than action regret, whereas women reported less different amount of inaction and action regret for romantic relationships. Evidently, relative to women, men report far more frequent regret having passed up sexual or dating opportunities. This sex difference has proved empirically robust across studies focusing more specifically on brief or casual sex encounters (Eshbaugh and Gute 2008; Fisher et al. 2011; Galperin et al. 2013) and reproduced in a more sexually liberal, less religious, and gender-equal nation (Bendixen et al. 2017; Kennair et al. 2016, 2018). To illustrate, Galperin et al. (2013) found in a national US sample covering 22,815 heterosexual participants (Of these, 6264 men and 6470 women reported their level of regret for their most recent casual sex encounter, and 7351 men and 6784 women reported on their level of regret passing up casual sex.) that men (43%) more than women (26%) reported that they regretted having passed up their most recent casual sex opportunity ($d = 0.60$). Moreover, relative to men (22%), more women (47%) regretted their most recent casual sex encounter ($d = 0.73$). Applying identical materials, the magnitude of these sex differences was reproduced in three separate student samples, one American and two

Norwegian (Bendixen et al. 2017; Kennair et al. 2016). However, in these samples of younger participants, there were generally less regrets related to passing up the most recent casual sex encounter. It is important to note that people do not in general regret casual sex, but the research attempts to answer the question: why do people regret casual sex, when they indeed do regret?

These findings are expected from a sexual strategies theory approach to sex differences in sexual behavior (Buss and Schmitt 1993), as there are stable differential adaptive consequences of casual sex for each of the sexes across our species' evolutionary history. This same approach predicted sex differences in negative postcoital emotions (Fernandes et al. 2016) sometimes referring specifically to affective shifts or changed attraction following sexual intercourse (Campbell 2008; Haselton and Buss 2001).

Sexual strategies theory predicts that men would report more casual sex inaction regret than women do, since they should not wish to forego short-term reproductive chances, as men may have greater reproductive success due to multiple matings. There are no comparable reproductive benefits for women who pursue multiple sexual partners. On the contrary, it is expected that women might, due to the greater costs involved in becoming pregnant, both show greater choosiness but also have greater reason for regret due to any cues or indications of incurred costs (including partner's lack of interest in committing after sex).

Evolutionary Psychological Theory of Casual Sex Regret

Galperin et al. (2013) suggested that casual sex regret is a sex-linked adaptive emotional response with the specific function of flagging maladaptive choices related to sexual encounters. The functional output would therefore be more adaptive future choices, resulting in less future regret. There is currently no evidence of actual behavioral change due to casual sex regret, although there is some research on the intention to change behavior due to regret in lab settings on consumer behavior (see Roese et al. 2007, for comments on

the necessity to alter behavior due to regret). Galperin and colleagues are explicit about the necessity that regret needs to have behavioral consequences to be able to have evolved or to be adaptive.

Predictors of Casual Sex Regret

Beyond sex, there may be a number of factors associated with regret having had and having passed up casual sex. Galperin and colleagues (2013) found that sex differences in regret having had casual sex held up across groups of differing sexual orientations but that both lesbian and bisexual women reported less casual sex regret. For men the level of casual sex regret did not differ between hetero-, bi-, and homosexuals. Relative to heterosexual women, lesbian and bisexual women also reported regretting passing up casual sex more. In their multiple regression analyses of heterosexuals, Galperin et al. (2013) found no age effects for neither action nor inaction regrets, but coupled respondents tended to report more action regret and less inaction regret compared to singles. In addition, higher levels of education tended to be associated with less inaction regret, but the effects were small and did not affect the overall sex differences. Sex differences in action and inaction regret were also smaller in gay/lesbian and bisexual samples compared to heterosexual samples.

Galperin and colleagues (2013) hypothesized that some social or proximate factors might moderate or exacerbate the above sex differences in casual sex regret. These included worry about becoming pregnant, which would be expectably higher in women, and level of physical gratification, which was expected to be lower in women. Here one needs to consider a caveat; accounting for any proximate factor that is related to sex in a statistical analysis may effectively reduce any sex differences in the level of casual sexual regret. Still, when considering sex differences, one needs to show constraint when *explaining* differences in one biologically sex-linked psychological trait or disposition with predictors that also are sex-linked psychological traits or dispositions. This might in

many cases result in the variance due to sex that is accounted for by proximal sex-linked factors (as in a mediator model); but it is conceptually equivalent to the proverbial “throwing the baby out with the bathwater.” A better analytical strategy would be either to perform separate analyses of predictors of sexual regret for women and men or to add an interaction term to examine if the effect of a main predictor of regret is moderated by participant sex.

Two studies covering three separate samples examined what proximate factors may be associated with casual sexual regret (Bendixen et al. 2017; Kennair et al. 2016, 2018). These studies inform us about the question why women regret casual sex more than men do and why men regret passing up sexual opportunities more than women do. In their first paper, Kennair et al. (2016) included three measures of worry (pregnancy, STI, and reputation), three measures of physical gratification (pleasure, orgasm achieve, and orgasm importance), and three measures of sociosexual orientation (behavior, attitudes, and desire). In the multivariate regression model, higher acceptance for short-term sex (SOI-attitudes), increased sexual pleasure, and less worry about reputation all predicted lower levels of regretting having had casual sex in women. For men, more sexual pleasure and stronger desire for casual sex partners predicted lower levels of casual sex regret. Women and men who worried about their reputation following casual sex reported less regret passing up casual sex opportunities. In addition, women who had higher acceptance for casual sex reported higher levels of regret passing up.

In their second study, Bendixen et al. (2017) analyzed comparable samples of Norwegian and American students. Predictors were level of religiosity (religious beliefs and adherence to religious doctrines) and the three sociosexual orientation dimensions (behavior, attitudes, and desire) of SOI-R (Penke and Asendorpf 2008). The two national samples differed predictably in levels of religiosity and sociosexuality, given expected cultural differences in religiosity and sexual liberalism. American students were far more religious than Norwegian students were

($d = 1.19$) and reported moderately lower levels of SOI-behavior and SOI-attitudes. Despite this, the level of regret having had casual sex or passing up casual sex was similar across nations. In addition, the sex differences in action and inaction casual sex regret found in Kennair et al. (2016) were reproduced in both the Norwegian and the American sample. Higher levels of religiosity predicted somewhat higher levels of regret having had casual sex and somewhat lower levels of regret passing up casual sex opportunities. As for the above study, higher acceptance for casual sex and more desire for casual sex (SOI-attitudes and SOI-desire) predicted lower levels of regret having had casual sex and higher levels of regret passing up. These effects were general and not moderated by neither participant sex nor nation.

The third and most recent study (Kennair et al. 2018) examined the effect of a number of additional proximate factors for regret having had casual sex. The study covered the same measures of worry and physical gratification as in the first paper. New, additional predictors included three domains of disgust (sexual, pathogen, moral), two items on feeling pressured to have sex, two items on the sexual competence of the partner, and a single item on the level of initiative to casual sex. When controlling for sex and nation, regression analyses of separate predictors suggested that worry, feeling pressures, and disgust predicted higher levels of casual sex regret and that the associations were higher in women than in men. Further, gratification, competence, and initiative predicted lower levels of casual sex regret. Again, the associations were stronger for women than for men. When regressing casual sex regret on all six predictors in a multivariate model, disgust turned out to be a particularly strong predictor. A variable that combined the level of gratification and competence was also significantly associated with regret, along with worry and initiative. In the multivariate model, the only sex-differentiated predictor was initiative; there was no effect of this for men. None of the other predictors was moderated by either sex or nation. Additional analyses of three domains of disgust showed that moral disgust turned out to be most important. Despite national differences in level of worry,

disgust, sexual competence, and the other predictors, the proximate factors associated with regret having had casual sex were similar across the Norwegian and the American samples.

Future Research and Unanswered Questions

Despite having reproduced the predicted sex differences in action and inaction casual sex, along with repeated attempts to examine personality and proximate factors related to sexual regret, it is worth noting that one has not tested the adaptive hypothesis suggested by Galperin et al. (2013). Such testing would require data that show evidence of regret predicting later increase in adaptive choice or behavior. For example, one might find that while controlling for different factors such as age or changing from single status to long-term committed partner status, those who have regretted most in earlier measures show the greatest changes in satisfaction with later mate choice. Alternatively, maybe they will show greatest decrease in new short-term partner or greatest likelihood of choosing to enter committed long-term relationships. In some way, higher levels of regret at any point need to predict subsequent more adaptive choice followed by lower levels of regret. The adaptive hypothesis thus needs testing in studies using longitudinal designs. The alternative prediction might be that different levels of regret represent individual differences in likelihood of regretting, including metacognitive beliefs about the benefits of regret (as the adaptive hypothesis actually is an example of), or individual differences in the likelihood of engaging in casual sex and thus having regrets, but without any feedback that results in behavioral change.

Further, there is a need to consider in greater depth what factors may predict different levels of inaction regret. Kennair et al. (2016, 2018) focused mostly on predictors of action regret, considering what likely predictors – theoretically and empirically – that would reduce or increase regret in men and women. Factors associated with regret passing up casual sex are clearly under-

researched. Given men's higher levels of inaction regret, future research need to include a variety of possible factors and examine the extent these affect inaction regret differently for men and women. Finally, possible effects of being intoxicated (alcohol or other substances) during casual sex on casual sex regret need to be considered fully in future research.

Conclusions

The sex differences in casual sex regret are robust. Men regret casual sex inaction more than women do, and women regret having had casual sex more than men do. This finding is not surprising from an evolutionary psychology perspective, as there have been stable differences in adaptive costs and benefits to the two sexes in engaging in casual sex.

Recent research on multiple factors have provided us with insights into what predicts both casual sex action and inaction regret. What predicts casual sex regret appears to be largely invariant across cultures that differ in three relevant dimensions: religiosity, sexual liberalism, and gender equality. The major predictors of casual sex inaction regret are unrestricted attitudes toward – and stronger desires for – casual sex. The major predictor of casual sex action regret is disgust; the largest single sex-differentiating factor is the degree to which one took the initiative to having casual sex, which only affects women's regret (less regret with greater initiative). Rather than less sexual gratification and pregnancy concerns, the results so far suggest that the proximate mechanisms involved in regret having had casual sex may be social in nature. The moral domain of disgust and the reputational aspect of worry appeared to be particularly good predictors of action regret. Throughout human evolutionary history, the transparency of men and women having short-term sexual relations might have been higher, and possibly sanctioned. Possibly, the social nature of factors affecting casual sex regret is a reflection of humans' hypersensitivity to signals of social exclusion or sanction.

Future research needs to specify better how the evolved mechanisms underlying sexual regret would have worked in the EEA. Thus far, there is no test of the evolutionary hypothesis. Such tests demand longitudinal studies. Current research sheds light on why people regret having or having passed up casual sex but cannot address the adaptive hypothesis, which might better explain negative postcoital emotions (Fernandes et al. 2016), rather than explain the function of regret. Future research needs to consider whether regret actually changes future choices in an adaptive direction.

Definition

Sexual reproduction refers to the mating system by which offspring with a double set of chromosomes (diploid) are created by the union of a set of chromosomes from the haploid gametes of one sex (male) with another set of chromosomes from the haploid gametes of another sex (female).

Introduction

We do not even in the least know the final cause of sexuality; why new beings should be produced by the union of the two sexual elements. . . The whole subject is as yet hidden in darkness. (Charles Darwin 1862)

Why did sexual reproduction evolve? When posed with this question one might think that sexual reproduction evolved because it is pleasurable. But this is no better an explanation for sexual reproduction than it is for hunger. Pleasure is something that natural selection attached to the activities that when engaged in led to the greater survival and reproduction of those individuals through evolutionary time.

Another potential answer to the question of why sex evolved is that it allows organisms to produce offspring. However, organisms with non-sexual forms of reproduction, such asexual reproduction, also produce offspring. In fact, asexual

organisms produce more offspring and at a faster rate than organisms that reproduce sexually. Additionally, asexual reproduction is not as costly as sexual reproduction (Roze 2012). The costs of reproducing sexually include finding a mate, engaging in courtship practices, and combining gametes from distinct individuals, among others (Roze 2012). Therefore, it appears that the cost-benefit ratio of sexual versus asexual reproduction in terms of the ultimate currency of natural selection – that is, reproductive fitness – is in favor of asexual reproduction. However, sexual reproduction has been widely favored by evolution and is the major reproductive system found throughout multicellular organisms in nature (Otto 2008).

From an evolutionary perspective, that sexual reproduction is pleasurable and that it leads to offspring are both answers to proximate- rather than ultimate-level questions about the purpose of sexual reproduction. The ultimate question regarding the origins of sexual reproduction is why did it evolve in the first place? Why was sexual reproduction favored throughout evolutionary history over the alternatives? Far from quick answers, this problem has eluded researchers for decades and has inspired some of the greatest evolutionary researchers in history, such as Ronald Fisher, William Hamilton, John Maynard Smith, and George Williams, to rise to the challenge.

The Origins of Sex

A complete understanding of how sexual reproduction evolved requires tracing evolutionary history back billions of years to the origins of life itself. Data from molecular sequencing studies have made it possible to date the origin of life to somewhere between 3.5 and 4 billion years ago (Weiss et al. 2016). The first life form, the most recent common ancestor of all of life, was likely a bacteria-like, intermediate organism being the common ancestor of the two major domains of life: bacteria and archaea (Weiss et al. 2016). Newer analyses have found support for the hypothesis that eukaryotes – organisms that eventually gave rise to all multicellular organisms such

as animals and plants – arose from prokaryotes, more specifically, from the domain archaea (Raymann et al. 2015; Williams et al. 2013).

In contrast to prokaryotes, eukaryotes do not strictly reproduce asexually, but also sexually. In other words, prokaryotes are obligately asexual, whereas most eukaryotes are facultatively sexual. Therefore, the origin of eukaryotic life is closely associated with the origin of facultative sexual reproduction, which is asexual reproduction with occasional sexual cycles (Dacks and Roger 1999). Eukaryotes sexually reproduce by complementing the system of mitosis or cell division – resulting in two genetically identical cells arising from one – with meiosis. Contrary to mitosis, meiosis consists of two rounds of cell division resulting in four daughter cells each of which possess only one set of chromosomes from the parent. In other words, meiosis results in four haploid cells, known as gametes. Gametes from two sexes combine to create a zygote.

Dacks and Roger (1999) show that the most parsimonious interpretation of their phylogenetic tree of eukaryotic taxa is that facultative sexual reproduction is the ancestral sexual cycle of eukaryotes. They speculate that because facultative sexual reproduction is characteristic of all protist eukaryotes, then obligate sexual reproduction in eukaryotes may be intertwined with multicellularity. Additionally, Goodenough and Heitman (2014) argue that the last eukaryotic common ancestor was sexually reproductive based on several studies that found evidence of genes exclusively involved in meiosis in all the main eukaryotic radiations. Goodenough and Heitman (2014) also describe several gradual changes that were likely taking place in between the transition from protoeukaryote to the last eukaryotic common ancestor that was sexual. One such change was cell-cell fusions, which result in greater chromosome number, likely a key prerequisite for meiosis to take place (Goodenough and Heitman 2014).

Additionally, there is evidence that many current day asexual eukaryotic organisms evolved from sexual ancestors. For example, the asexually reproducing protozoan *Trichomonas vaginalis*, a cause of vaginal infections, likely evolved from a

sexual ancestor (Malik et al. 2008). Research has shown that *Trichomonas vaginalis* contains genes that are exclusively used for meiosis, a necessary part of sexual reproduction, and that these genes were already present early in eukaryotic evolution (Malik et al. 2008). Another example is the unicellular eukaryotic pathogens microsporidia that are a common cause of human infections. They include many asexual species. Evidence suggests, however, that they evolved from a zygomycete fungus ancestor and possess genes related to sexual reproduction that are similar to the sex genes that zygomycetes possess (Lee et al. 2008).

Far from being an evolutionary novelty, sexual reproduction appears to be as old as the appearance of eukaryotes. Studies that analyze molecular and genetic data of these early eukaryotes show that evolutionary processes must have favored sexual reproduction, so much so that it has become the dominant mode of reproduction among eukaryotic organisms. However, a deep problem remains.

The Problem of Sexual Reproduction

The central problem of the evolution of sexual reproduction arises from its ubiquity throughout nature on one hand, and its enormous and obvious costs on the other. Over 99% of multicellular eukaryotes reproduce sexually making it the most commonplace mating system in multicellular eukaryotes (Otto 2008). However, from the level of the gene's eye view, sexual reproduction is extremely problematic.

Imagine a population of 100 sexually reproducing organisms with an equal ratio of males to females (50:50). Assuming the first generation reproduces once, a maximum of 50 offspring can be produced. Compare this to an asexual population of 100 organisms in which each individual organism can produce offspring. If the first generation reproduced once, a maximum of 100 offspring would be produced. This results in the per capita birth rate of an asexual species being twice that of a sexual species. And so, an asexual mutant that arises in a sexual population should double in frequency each

generation and quickly replace the sexual population. This problem is known as the twofold cost of sex. It is also referred to as the “cost of males”, since in sexually reproducing species, males do not directly produce offspring (Maynard Smith 1978).

This problem was first formulated and described in depth by John Maynard Smith (1978). From the point of view of natural selection at the level of the gene, sexual reproduction should never evolve, and yet, it has, hence the longstanding problem in evolutionary biology. How could sexual reproduction evolve and, in fact, become vastly ubiquitous throughout nature given the enormous costs of sexually reproducing?

Genetic Diversity as an Outcome of Sexual Reproduction

One of the first evolutionary theories for sexual reproduction was the variability of offspring hypothesis first proposed by the German biologist August Weismann in the 1800s (Weismann 1889). This hypothesis states that sexual reproduction results in the combination and rearrangement of genes that provides necessary variability for selection to act. Due to the continuous mixing of genes under sexual reproduction, offspring will have more variable phenotypes, which allows for selection to act and for populations to evolve more rapidly.

This hypothesis arises from the fact that compared to asexual reproduction which produces genetically identical offspring, sexual reproduction results in genetically unique offspring. A large part of this genetic variation comes from genetic recombination during the first cell division stage of meiosis. During genetic recombination, homologous chromosomes within the two haploid cells pair and exchange genetic information creating new allelic combinations and hence genetic variability. This results in all gametes within just one individual being genetically unique from each other. Moreover, sexual reproduction leads to fertilization, whereby gametes from one parent are combined with the gametes from the other, resulting in genetically unique offspring.

Therefore, according to this theory, populations of sexually reproducing organisms will produce offspring with more variable phenotypes allowing for the faster and more effective attainment of favorable mutations and response to environmental changes. This process should benefit the population, but not necessarily the individuals within it, and is thus a group-selectionist evolutionary theory. Other researchers have revised and reformulated the theory considering new scientific tools and evidence, such as population genetics, and mathematical formalisms to model the evolutionary dynamics under specific conditions (Fisher 1930; Muller 1932; Crow and Kimura 1965).

Maynard Smith (1971) refers to the variability hypothesis of sex explanation as the “long-term explanation” for sex. Fisher (1930) and Muller (1932) contribute to this long-term explanation of sex by describing how if two favorable mutations arise separately in a population, sexual reproduction allows for them to be incorporated into individuals. In contrast, the absence of sexual reproduction in asexual populations ensures that favorable mutations are stuck within their common descent lineages since there is no gene mixing between unrelated individuals.

Researchers putting the variability hypothesis of sex, also known as the “Weismann effect,” to the test have found support for it as an explanation for why sex may have been favored by evolution. Goddard et al. (2005) found support for the Weismann effect by genetically engineering some yeast to be sexually reproducing and others to be asexually reproducing and raised them both in a stressed, low nutrient diet. The sexually reproducing yeast were able to adapt faster to the new environment with greater rate of growth than the asexual yeast. Indeed, many other studies support Weismann’s variability of sex hypothesis (Becks and Agrawal 2010, 2012; Colegrave 2002; Cooper 2007).

Crow and Kimura (1965) add quantitative models and mathematical formalisms to the variability of sex hypothesis. They model the incorporation of favorable mutations in populations with and without recombination (corresponding roughly with the modes of sexual and asexual

reproduction, respectively) and represent parameters such as population size, generation number, selective advantage of the mutation, and the rate of favorable mutations. They show that the advantage of sex is greatest when the population size is large, when the rate of mutations is high, and when the selective advantage of the mutations is small. In other words, sex has less of an advantage over asexual reproduction if favorable mutations spread too quickly through a population (i.e., if the selective advantage is high and if the population size is small) and thus are wasted, because there is not enough time for them to be incorporated.

Crow and Kimura (1965) also add important limitations and nuance to the notion that sexual reproduction leads to greater genetic variability compared to asexual reproduction. These nuances include the fact that the number of genetic combinations produced in any generation is limited by the population size. Additionally, while recombination leads to several unique genetic combinations, recombination also breaks up the number of combinations, reducing the amount of variability.

Maynard Smith (1971) addresses potential shortcomings in the model of Crow and Kimura (1965) and also raises a counterargument to the “long-term explanation of sex” originally voiced by Williams (1966), which is that it requires selection to act at the level of the group or species rather than at the level of the individual or the gene. Maynard Smith (1971) calls Williams (1966) explanation the “immediate advantage” explanation for sex, in that it posits that sexual reproduction confers an immediate advantage in terms of creating variable offspring, some of which will be high in fitness. Maynard Smith (1971) models this explanation and finds it lacking, because if true it would suggest that environments must vary tremendously for sexual reproduction to be immediately advantageous. He states it thus “sexual reproduction is an immediate advantage only if the correlations between selectively relevant features of the environment commonly change sign between one generation and the next” (Maynard Smith 1971, p. 332). Indeed, many studies have found evidence that changing environments have

something to do with the evolution of sexual reproduction (Colegrave 2002; Goddard et al. 2005; Cooper 2007).

Purging Bad Genes

Another major theory for the evolution of sexual reproduction is that sex allows for a way to effectively remove “bad” genes – that is, mutations that have a negative impact on an organism’s fitness – from a population. Muller first described this process in what has come to be called “Muller’s Ratchet” (Muller 1964). Muller’s Ratchet refers to the problem of asexual species accumulating deleterious mutations in an irreversible manner. Deleterious mutations accumulate because in an asexual species, the offspring end up carrying at least just as many mutations as their parents because of the absence of recombination. Muller (1964) proposed this as one of the reasons why sexual reproduction may have been favored over asexual reproduction, as it allows for the purging of deleterious mutations through recombination, resulting in offspring with unique combinations of genes and traits.

Experimental evidence for this theory is mixed at best. Ridley (1993) describes how this theory requires unrealistic expectations about nature such as mutation rates to be higher than they really are and works too slowly when pitted against the rate of asexual reproduction. Even if there were ample evidence of the purging effect of sexual recombination on deleterious mutations, this alone only explains one effect of sexual reproduction and not the reason for why it evolved in the first place (Ridley 1993).

Pathogen Resistance

Perhaps the best theory for the evolution of sexual reproduction comes not from the preservation of good genes, the removal of bad genes, or the creation of variable offspring, but from parasites. Many researchers seemed to have confused a consequence of sex, variability, with its purpose. But as shown above, variability can mean many

things. The key question regarding the variability that sexual reproduction leads to is the following: what is the variability for?

Previous models of the evolution of sexuality posited a correlation between environmental uncertainty and sexuality (Maynard Smith 1971). However, when biologist Graham Bell assessed various species in nature and the relation between their sexuality and environmental harshness and uncertainty, he found the opposite of the expected pattern (Ridley 1993). Asexual species tended to live in the highly variable environments of freshwater compared to saltwater. They tended to live at high latitudes and high altitudes, where weather is more variable and harsher, and on disturbed ground.

It turns out that the kind of variability that sex leads to might be for the purpose of thwarting a variable and ever-changing foe, parasites. Maynard Smith (1971) showed that for an obligate sexual population to be favored over an asexual population, the environments would have to change radically every generation. Host-parasite coevolution might provide the radically changing environmental conditions that Maynard Smith (1971) speculates must be in place in order to sex to evolve.

Many are familiar with the idea of coevolutionary arms races between predators and prey and between hosts and parasites. Coevolution is a process in which two or more species affect each other's evolution through reciprocal evolutionary changes. The change in one species confers selective pressure on another species, causing the other species to evolve countermeasures that, in turn, confer selective pressures back on the other species, and so on. For example, in predator-prey interactions, a predator is selected to possess adaptations that help enable the catching, killing, and eating of its prey. However, the prey also possesses anti-predator adaptations, such as keen senses to detect a predator and running speed to escape from it. Better antipredator adaptations in the prey place selective pressures on the predator for better antiprey adaptations, and vice versa, resulting in a coevolutionary arms race.

This dynamic is also in place for host-parasite coevolution. Better immune systems protect a

host from infectious parasites, which places selective pressure on parasites to fool the host's immune system and be more effective and infectious. More parasitic parasites then, in turn, place selective pressure on the host's immune system, and so on, in a coevolutionary arms race.

This idea of coevolutionary arms races came to be known as the Red Queen hypothesis after Lewis Carroll's book *Through the Looking Glass*, where the Red Queen takes Alice on a run that never seems to go anywhere. It was first proposed in an evolutionary biological context in Van Valen (1973) as a hypothesis for why many species' probability of extinction does not depend on the lifetime of the population. Rather, many populations of organisms remain extant or go extinct by constantly adapting to changing environments including coevolving with other antagonistic species. In other words, the Red Queen hypothesis gets its name from the fact that organisms continually evolve to changing environments, which include other antagonistic species, but there is no progression. There is constant adaptation just to stay in place.

In the case of the evolution of sexual reproduction, the Red Queen hypothesis has been mathematically modeled to understand both how sex evolved and how it has been maintained considering its twofold cost (Hamilton 1980; Hamilton et al. 1990). Evidence from these models show that even with conditions similar to that of human evolution – namely, relatively low fecundity and long generational time spans – sexual reproduction is favored over asexual reproduction in the presence of parasites and hosts with resistance genes to the parasites. Asexual hosts with unfavorable genes were more often driven to extinction. However, sexual hosts with unfavorable genes at one time can store, reshuffle, and reuse these genes at another time when they are needed to thwart parasites (Hamilton et al. 1990). And so, evidence suggests that sexual reproduction via recombination leads to unique genetic arrangements in offspring each generation. This genetic reshuffling process of sexual production provides sufficient change to effectively thwart parasites that rapidly adapt to host genotypes each generation via their extreme fecundity and short

generational time spans (Hamilton 1980; Hamilton et al. 1990; Ridley 1993).

Conclusion

While sexual reproduction is extremely common in nature, its evolutionary explanation has eluded researchers for decades, going all the way back to Charles Darwin. Most explanations of sexual reproduction have drawn on one of the most striking differences between sexual reproduction and asexual reproduction, namely, that sexual reproduction creates genetic variability.

One variant of this hypothesis is that sexual recombination results in a unique rearrangement of genes in offspring, which provides the fuel for natural selection to act, allowing more variable populations to evolve more quickly. Other researchers refined this idea using mathematical models and formalisms (Fisher 1930; Muller 1932; Crow and Kimura 1965). Fisher (1930) argued that sexual reproduction allows for the incorporation of beneficial mutations, whereas mutations in asexual organisms would remain in a single line of common descent. Others reformulated this hypothesis in terms of benefits for individuals rather than populations, since greater variation can result in offspring with greater fitness (Williams 1966). Others explained that the benefits of sex come from the need for rapid adaptation to varying environments (Maynard Smith 1971). Another potential explanation for sexual reproduction is that it allows for the effective purging of bad mutations from the population (Muller 1964).

The parasite-resistance theory of sexual reproduction takes many elements from these previous theories but in the service of a different problem, namely, thwarting parasites. Indeed, evidence does support this theory, such as research in snails (Lively and Dybdahl 2000). However, even this theory may not tell the full story of how sexual reproduction evolved. It is conceivable and very likely that there is no single explanation for the evolution of sex, given that it has evolved numerous times throughout nature and is found in organisms as different from each other as single-celled protists and human beings.

Future research should continue to complement mathematical models of evolutionary dynamics with natural experiments to put the different theories and hypotheses of sexual reproduction against the evidence of nature.

Definition

When the selective force in evolution is specifically the behaviors of potential mates and rivals, it is often distinguished as *sexual selection*, as contrasted with other selective forces. A key reason for doing this is because sexual selection can lead to many distinct results that reflect the contrast between sexual success (reproduction) and survival success. Survival is necessary for reproduction, but not sufficient by itself. Sexual selection helps to account for non-survival aspects of between-sex attractiveness between potential mates (e.g., ornaments, displays, and other courting features) and features related to within-sex competition (e.g.,

weapons, sexual dimorphism). The tension between survival and reproduction sometimes emerges in the form of “handicaps,” costly, survival-harming traits that an organism possesses in order to honestly signal to potential mates the ability to nevertheless thrive.

Introduction

Evolution by natural selection focuses on adaptations and the ways in which useful mutations have led, over the course of evolutionary history, to the survival of the fittest. Of course, in this case, “the fittest” does not necessarily mean an individual that is our cultural idea of “physically fit” but more an individual that knows how to survive and adapt best to their environment. When discussing evolution, the idea of fitness is more specifically based on the process in which mutations useful to individuals within their environment are passed down via their genetics until those without these mutations were no longer part of the population. For example, Darwin noted on the *Voyage of the Beagle*, in regard to the finch beaks on the Galapagos Islands, natural selection is the mechanism for evolutionary change and progress. Each island had a finch beak variant that was beneficial to that specific island’s ecosystem (i.e., food source). On the islands where seeds were a primary food source, the finches had large crushing bills – yet on the islands where insects were a primary food source, the finches had narrow probing bills to aid in the extraction of insects from trees. Another popular example of natural selection is that of peppered moths in Manchester England and the influence of the industrial revolution: Prior to the industrial revolution, the typical phenotype of these moths was white (with only about 1% of the population being black) because it helped them blend into the white lichen on the trees, increasing their camouflage and reducing likelihood of predation. During and after the industrial revolution, the trees became covered in black soot, and the black peppered moths (which previously had only made up 1% of the population) suddenly had the survival advantage. The fitness of the

phenotypic variations in the peppered moths changed due to a change in the environment, ultimately resulting in a change in allelic frequency due to natural selection. Importantly (included in both examples mentioned above), variation within a species must be present in order for natural selection to operate. Random mutations came about that gave individuals within a species a survival advantage, and over many generations this trait was continuously selected for due to its fitness.

Natural Selection Versus Sexual Selection

Natural selection is not the only selection that takes place in the process of evolution. In fact, it is sometimes the case that the presence of specific traits seems counterintuitive to an individual's fitness. Take peacocks, for example – the presence of their ornate elaborate trains was said to have kept Darwin up at night. From a strictly natural selection perspective, these traits made absolutely no sense: standing out to predators has the potential to be incredibly risky – yet, generation after generation we see individuals within various populations with traits that seem counterintuitive to their survival/fitness (Gray and Garcia 2013). Whereas natural selection is the evolution of characteristics that provide a survival advantage, sexual selection is the evolution of characteristics that provide a reproductive advantage (even if it sometimes means encroaching on a survival advantage). Simply put, both natural and sexual selection play important, but distinct roles as mechanisms of evolution. Some may argue that sexual selection is the more important mechanism of recent selection (within our species), simply due to the fact that it is (or was until evolutionarily recently) necessary for the flow of our genetics through the generations (e.g., Miller 2000). In an ultimate sense, survival is only important in light of reproduction. It is easy to comprehend the ways in which certain characteristics may provide a survival advantage – better vision leads to better resource acquisition, better grip strength leads to safety, while in a tree, camouflage leads to being

able to blend into the surrounding environment. Yet, when it comes to characteristics that provide a reproductive advantage, it becomes less clear.

Sexual selection is based on attraction to an individual in some way, shape, or form. Certain traits (like clear skin and facial symmetry) are cross culturally considered attractive due to their links to underlying health, fertility, and overall fitness (Gray and Garcia 2013). Sexual selection operates based on traits that members of the opposite sex find attractive, whereas natural selection is based on traits that help overcome some sort of adaptive problem. Attractiveness can take many forms – typically ascertained when looking at any battery of terms used to describe mate value. Sexual selection tends to focus most on physical, facial, body, vocal, and even behavioral attractiveness (Bressler et al. 2006; Frederick and Haselton 2007; Gallup and Frederick 2010; Greengross and Miller 2008, 2011; Miller 2000; Singh 1993; Hughes et al. 2004). Although there are nonphysical factors that are related to assessments of attractiveness (e.g., financial status), physical and behavioral traits are most directly related to the inner workings of an individual and can possibly be a cue to the health and well-being of that person. This is especially important for reproductive purposes.

The Science of Sex Appeal and Human Sexual Selection

Dawkins (1976) presented an evolutionary argument that each and every member of all living species on the planet exists to pass on its genetic material to subsequent generations (the gene-centered view of evolution). Furthering this theory, we must assume that we do not want to pass on our genetics to offspring who will not survive, and thus we get to the *why* of sexual selection. Species do not have meetings wherein all the members of one sex get together and decide only to mate with those who possess a certain trait – these traits are adaptive in nature and not consciously decided upon. The science of sex appeal, across all species, comes down to a single fact about attractiveness: what one sex finds attractive in the opposite sex is linked in some way to

underlying health and fertility. Sexual selection is therefore based on selecting mates of high fitness – healthy and fertile individuals who will be good partners for making offspring who will ultimately serve as a way to pass along our own genes. These offspring will be healthier and more likely to live to the age of reproduction themselves, which increases an individual's overall reproductive success. Examples of attractive features being linked to underlying health and fertility can be found in various forms (Gallup and Frederick 2010). In humans, some traits found attractive in women (by heterosexual males) include a relatively low waist-to-hip ratio (WHR) which, when closest to 0.7, is universally found to be the most attractive body shape across a wide range of body sizes and weights (Singh 1993; Gallup and Frederick 2010; Gray and Garcia 2013). This 0.7 ratio has also been linked to higher fertility; thus, the feature is physically attractive due to a fundamental relationship to fertility.

Another example (Gallup and Frederick 2010) is gluteofemoral fat – a type of fat located around the thighs and buttocks of a woman, which is thought to provide brain-building resources, for both a mother and potential offspring. Sir Mix-a-Lot, an early 1990s hip-hop artist, described his love of big butts in a surprisingly catchy, enduring pop song entitled *Baby Got Back*. Sir Mix-a-Lot, a rapper who wrote his one-hit wonder and released it in 1992, was almost certainly not thinking about the fertility or fecundity related to the “back” that he sang about, yet his lyrics demonstrate a desire for features known for fertility and fitness. “Oh’rumpo smooth skin” may sound like Rumpelstiltskin or a way to describe the derrière of a woman using a word other than “butt” or “back,” but it gets at another physical aspect related to health – smoother skin often suggests less mutations and healthier genetics. Though a bit tangential, fascinatingly, *Baby Got Back* also depicts other aspects of mating – including mate poaching, wherein a committed individual is “stolen” by a new mate. “Some brothers want to play that hard role/And tell you that the butt ain’t go! / So they toss it and leave it/And I pull up quick to retrieve it” – Sir Mix-a-Lot essentially described a mate poaching scenario.

Female bodies are clearly also not the only traits which matter in terms of sexual selection. For male bodies, shoulder-to-hip ratio (SHR) is an aspect of body configuration related to mating. Broad shoulders and narrow hips (high SHRs) are – in some ways – the male correspondent to female large hips and small waists. A student once described the physique as “the Dorito body,” though “Superman Torso” seems more easily accessible as slang for the body configuration. Shoulder-to-hip ratios also are thought to be an indicator of fitness, with broad shoulders and narrow hips in males being linked to higher levels of testosterone (Gangestad and Scheyd 2005; Gray and Garcia 2013; Hughes and Gallup 2003). In fact, Hughes et al. (2004) found that ratings of vocal attractiveness were highly correlated with optimal indices of WHR and SHR and proposed that this link is due to sex hormones shaping these sexually dimorphic configurations (like estrogen and testosterone). From a costly signaling perspective, high levels of testosterone can be harmful to an individual's body because it weakens the immune system, so if an individual is displaying signs of relatively high testosterone, this may be deemed as “attractive” simply because of the cost vs. benefit ratio. Males with higher SHRs tend to be stronger and more aggressive, thus more likely to win in intrasexual competition for mates. Additionally, high SHR males have been found to have sex earlier and have a higher number of overall sex partners throughout their lifetime than males with lower SHRs. Frederick and Haselton (2007) proposed that females have an evolved attraction to muscles and overall physical prowess in men – muscularity requires extensive calories and testosterone to maintain. This links back to a “handicapping” theory that a sexually selected trait can actually be detrimental to survival (testosterone compromises immune function, and increased muscle mass demands a lot of energy). However, overcoming these costs may also serve as a signal of better health and overall fitness quality, demonstrating that an individual is nevertheless able to successfully maintain their fitness as well as their overall health.

Aside from body shape, research has found that we have an (evolved) preference for attractive

faces. How individuals rate attractiveness in faces is largely independent of many variables that tend to mediate preference (e.g., gender, culture, sexual orientation, age). In fact, there is a considerable degree of cross-cultural consensus regarding facial attributes that are considered attractive (Gallup and Frederick 2010; Thornhill and Gangestad 1999). Importantly, research has found that there are links between facial attractiveness and health, intelligence, and fertility. In other words, facial attractiveness seems to be an honest phenotypic indicator of genetic quality. Henderson and Anglin (2003) sampled old high school yearbook photos, matched them with obituary records, and had college students rate the photos for attractiveness. Both men and women that were rated as attractive lived longer on average. Longevity is an indicator of health, and importantly, the transmission of the genes that code for longevity is highly heritable.

In addition to longevity, there have been positive correlations between intelligence and fertility as well. Using an archived sample of 425 Army veterans, Arden et al. (2009) found a significant positive correlation between semen quality and general intelligence. Again, due to the idea that various forms of intelligence can be highly heritable, it is adaptive to select a mate who will pass on these genes to future generations. Furthermore, there have been many findings indicating that there is a link between ratings of facial attractiveness and fertility in both males and females. Soler et al. (2003) took photos of participants' faces and collected semen samples from college students. The males that were rated as more attractive had a higher sperm count, motility, and morphology (the composite index of sperm quality) when compared to males that were rated as less attractive. Just as optimal shoulder-to-hip and waist-to-hip ratios were linked to fertility (as well as testosterone levels in males), attractiveness ratings of female faces were positively related to estrogen levels and reproductive health (Law-Smith et al. 2006).

Females are particularly interesting when it comes to the link between ratings of attraction and genetic quality because *concealed ovulation* is a factor as well. Though our closest primate

ancestors all have varying degrees of sexual swellings to notify potential mates that they are sexually receptive, human's cues to ovulation are much more subtle. It was historically thought that human females show no outward signs that they are in their fertile phase of their ovulatory cycle, but in actuality there are many physiological and behavioral cues that fluctuate slightly depending on where a female is in her cycle. Behaviorally, during peak fertility days, women were more likely to agree to dance with an attractive male confederate, show greater interest in going out to dance clubs and/or parties, and dress more provocatively (for a review on this research, see Haselton and Gildersleeve 2011). Physiologically, there are changes in body odor around ovulation, and males have rated these odors as smelling more pleasant than odors taken from other phases in the ovulatory cycle (known as the "stinky t-shirt studies" Thornhill et al. 2003). In a study on the effects of subtle ovulatory cues on males, Miller et al. (2007) found that lap dancers received substantially more in tips on high fertility days as compared to low fertility days. So, in a general sense, even though there is no *obvious* physiological display of fertility in humans, there are unseen, subtle cues that could influence mate selection.

Surprisingly, the use of specific types of humor can be an underlying indicator of genetic fitness and can also influence mate selection. Miller (2000) posits that the use of (appropriately timed) humor evolved as mental fitness indicator due to sexual selection via mate choice. Bressler et al. (2006) found that, although both sexes prefer someone with a "good sense of humor" as a potential mate, it means something slightly different to men and women. Women prefer mates who use humor, while men prefer mates who are receptive to their own humor – especially when it comes to intimate relationships. This suggests that sexual selection could have operated on men and women in different ways, resulting in a noticeable discrepancy in desire for various forms of humor in mates. Taking this a step further, Greengross and Miller (2008) attempted to get at the type of humor individuals use when interacting with potential mates. Evolved

mate preferences came to light when assessing a potential long-term mate with high status: in both males and females, individuals that used self-deprecating humor (i.e., “dissing oneself”) as opposed to other-deprecating humor (i.e., “dissing rivals”) were rated as more attractive. In summary, mate choice is influenced by a multitude of factors behind the scenes, but all of these factors have been subtly shaped by sexual selection.

Intrasexual Competition

What happens when two individuals are interested in the same potential mate? What if that potential mate is not interested in either of those individuals? Sexual selection occurs through two forms of competition: intra- and intersexual competition. *Intrasexual competition* is used to discuss competition within members of the same sex for access to the other sex. This can be either female competition with other females or male competition with other males. Whatever traits aid in successful competition among members of the same sex (such as size, strength, social charisma, etc.) will be selected for, and thus those who possess those traits gain a reproductive advantage due to an increase in access to the more desirable and/or a larger pool of receptive mates. Classic examples of intrasexual competition include the selection for large deer antlers (for males) used for fighting and to display dominance within herds of deer. Similarly, within humans, intrasexual competition typically plays out in terms of competition within males. We see this regularly in organized sports and the large industry that exists for boxing and MMA (mixed martial arts) fighting. In females, we also see indices of competition, but it is typically broken down into four distinct forms: self-promotion (displays of physical attractiveness), competitor derogation (making rival seems less attractive with rumors, etc.), competitor manipulation (downplay potential mate’s worth to rivals), and mate manipulation (remove potential mate’s attention from rivals) (Fisher and Cox 2010). Classically, it was thought that intrasexual competition existed solely in males due to the

differential investment in gamete production and parental investment. Consider the difference: females typically release one egg per month; males produce millions of sperm each day. Once sexual intercourse is over and a female conceives, the next 10 months of her life (but not necessarily the father’s life) is increasingly consumed by the growing demands of the fetus. This drastic difference in energy expenditure and parental investment is thought to drive males to be more intrasexually competitive due to the fact that females are the “choosier sex” (Trivers 1972).

Intersexual competition, on the other hand, is competition among members of the same species but *between* the sexes – in other words, one sex may exhibit preference for a particular trait, which gives members of the other sex who possess those traits a reproductive advantage (Buss 1995). Often, when a trait is selected for by one sex, we refer to the selection as *epigamic*.

Maladaptive-Seeming Traits that Are Adaptive for Sexual Selection

Sexual selection has seemed to be the answer for many adaptations that do not necessarily make sense for survival purposes. For example, why would male deer have tall antlers that could become stuck in trees and bushes? How is that possibly adaptive? At first glance, large antlers seem like a mistake; they may hinder survival by making these deer easier prey for predators. We understand now, though, that deer use their antlers for intrasexual competition for mates. Darwin noticed these traits that seemed to be counterintuitive to natural selection’s influence in evolution – upon pondering this anomaly in natural selection, he noted that there must be a reason for these hindering traits that species seemed to display. An overly simple analogy for this could be if a person had never before encountered a door. Now, this person would probably easily figure out that the door was an entry way into a domicile. They could understand it remaining closed, to keep out others. Imagine this person then attempts to open the door, only to find it locked. Assuming this

person does not assume that the locked door is simply another wall of the domicile and they realize that it can be locked and unlocked (perhaps after observing people going in and out), common sense would likely lead to the notion that the door may be closed off entirely (locked) in order to keep out those who are unwanted. This analogy is similar to the problems faced by scientists and naturalists when attempting to understand a trait that appears maladaptive. There is a thing, the door, but it locks and is often closed, therefore defeating its purpose of allowing people in and out of a structure. However, realizing it can be unlocked for friends and locked for foe suddenly makes the locking a reasonable and understandable aspect to the door. From this, we can begin to understand sexual selection – it is the caveat for natural selection’s adaptive traits. A trait may seem maladaptive at first glance, but is often adaptive according to the rules set forth by sexual selection, i.e., does this trait help with intrasexual or epigamic selection? If so, the trait can no longer be seen as maladaptive, as long as we uphold the notion that reproduction is the ultimate goal.

Sexual Selection in the Animal Kingdom

Sexual selection is more easily understood across the rest of the animal kingdom, rather than in humans, partly due to the fact that sexual dimorphism is often more easily observed in other species. *Sexual dimorphism* is a phenotypic trait difference between the male and the female of a species (driven by mating systems). Often when discussing sexual selection (or sexual dimorphism for that matter), the most salient example is the peafowl. Peafowl have a great degree of sexual dimorphism; the peahen is rather plain, while the peacock has a plumage of tail feathers that he spreads to show off when seeking a mate. This example gives insight to several aspects of sexual selection; first, we see the peacock tail as an example of a phenotypic trait which has been selected for due to the preference for said trait in peahens, which demonstrates intersexual selection. Second, the selected phenotypic trait may

be advantageous for accessing mates while also serving as somewhat of a hindrance to natural selection (how much easier must it be for a peacock to be caught by a predator, dragging his tail behind him, compared against the catchability of a peahen). Continuing with the peafowl example, we can examine epigamic selection’s outcomes – in other words, how does mate choice take place when sexual selection has occurred through intersexual competition? Peafowl (as with numerous species) begin their mating with a display in a lek. A lek is a place where animals that use mating displays come to show off their “goods” and to choose mates. Peacocks display their extraordinary tails, opening the feathers up like a paper fan, while peahens observe the peacocks and choose mates based on the quality of the peacock tail. Showing off a phenotypic trait is not the only way mating displays can be done – bowerbirds (small dark birds indigenous to New Guinea and Australia) show their mate value in a different way. Rather than parade a specific physical feature, they build nests at the lek, lining the little hut-like shelters with shiny, colorful objects. Female bowerbirds descend upon the lek and try out the nests, often visiting the same male’s creation numerous times before making a mating decision. The males exhibit their shiny and colorful objects for the females to view. This form of sexual selection brings us to *why* certain traits are selected.

One of the most interesting aspects of sexual selection in terms of traits that seem maladaptive is the *handicap hypothesis* (Zahavi 1975). The handicap hypothesis has many definitions, depending on the usage. First, the handicap hypothesis was said to stem from costly signaling – it has been discussed that signaling is a way for many species to begin the mate selection process. The more costly a trait is (e.g., a peacock’s large and luminous tail must make it terribly hard to escape from predators), the more “honest” and reliable it is, therefore making it more attractive. The cost-benefit analysis here shows the costliness of the trait and the likelihood of being noticed as a beneficial aspect. In the case of the peacock, the ornate nature of its tail is thought to correlate with the amount of point mutations that the peacock has – signaling genetic quality to potential mates. In

sum, the handicap hypothesis essentially demonstrates exactly the problem that sexual selection answers for natural selection – why do ostensibly maladaptive traits continue to be passed down to subsequent generations?

Costly Signaling in Humans

When it comes to costly displays in humans, it gets more complicated. Though plastic surgery and cosmetics could arguably be considered costly signaling, they are also both used as dishonest signals that are supposed to conceal the link between our genotype, phenotype, and environment. Instead, we turn to the idea that forms of body modification (including scarification) are used as a way to physically display our genetic fitness. Historically, scarring, tattooing, and piercing the body had ritualistic tribal origins and signified the passage into adulthood or other important life events. From a costly signaling perspective, if individuals (especially in pre-industrialized societies) open up their body to infection and various blood-borne diseases, it is extremely risky. Specifically, if bacterial infections are not addressed properly, it can lead to soft tissue infections, sepsis, and toxic shock syndrome – all of which are potentially life-threatening (Koenig and Carnes 1999). If an individual is able to heal properly, it means that their immune systems are healthy and viable enough to fight off foreign pathogens. It is hypothesized that in industrialized societies, due to access to modern medicine/healthcare, the costly displays in which body ornamentation takes place have increased noticeably in order to stand out to potential mates (known as the “upping the ante hypothesis,” Carmen et al. 2012). Additionally, body ornamentation could be potentially viewed as an extended phenotype due to the extension of our genes via behavior to stand out to potential mates as an indicator of fitness (known as the “human canvas hypothesis,” Carmen et al. 2012). From an ultimate, evolutionary perspective, sexual selection selects for behaviors that will increase the likelihood of finding a mate and producing offspring, resulting in the flow of genetic material

through the generations. Sexual selection has encouraged costly signaling.

How Humans Have Shaped Selection: Selective Breeding of Dogs and Cats

As humans, we have taken our understanding of evolution to another level and begun selectively breeding different species to get results which we consider favorable outcomes. A popular example would be the domestication of dogs and cats, ultimately resulting in an impressive array of phenotypic variations. A pug, a German shepherd, and a Great Pyrenees all share the common ancestor of the wolf, yet they are physically and behaviorally all very different. Interestingly enough, an experiment that began in the 1950s (and is still going today) in the Soviet Union/Russia led way to some interesting and informative findings regarding the relationships between genotypic, phenotypic, and behavioral traits. In 1959, Dmitri Belyaev and a team of researchers began selectively breeding red foxes for the retention of juvenile traits (tamelessness) throughout adulthood. By selecting for a behavioral trait, the researchers were essentially manipulating the natural and sexual selection of these foxes. Along with the selection of the behavioral trait came interesting phenotypic changes like spots in their coat color due to decreased adrenaline and floppy ears (Trut 1999). By attempting to isolate a specific feature of a species (in this case the behavioral trait of “tamelessness”), other traits essentially came along for the ride and began to typify that population.

Before humans began manipulating what was once a purely evolutionary outcome, sexual selection was perhaps the sole reason that specific traits which appeared to be detrimental to survival emerged in any given species. Since the human psyche is considerably complex, it should be no surprise that the ways in which we are attracted to one another is mediated by a multitude of variables, including sexual selection. Though humans have tried desperately to draw a thick line between us and the rest of the animal world, we actually share far more in common with the rest of the animal kingdom than we like to admit.

Conclusion

Sexual selection provides us with a way to understand what was once a seemingly puzzling phenomenon: the presence of traits that could apparently impede survival in one way or another. Natural selection was easily understood in terms of the effect of the environment on an individual's traits and attributes, but this limited our understanding of the power that *sexual* selection can have on the very same traits and attributes. Our preferences for specific traits in potential mates have been shaped in countless ways by sexual selection and will continue to evolve along with us.

²Smithsonian Tropical Research Institute and Escuela de Biología, Universidad de Costa Rica, San José, Costa Rica

Synonyms

Contests of aggressiveness; Male battles; Sperm competition

Definition

Direct competition between members of one sex (usually males), through contests of threats, battles, or sperm, to obtain reproduction with the other sex.

Introduction

There are traits in animals that are not related to ecological adaptation. These other adaptations are the outcome of sexual selection: intraspecific competition, usually between males for access to females and their gametes. Such competition takes

the form of displays to attract females, ritualized threats to dissuade competitors, or actual physical fights. Darwin (1859) recognized these processes as being different from natural selection; in his own words: “Sexual Selection...depends, not on a struggle for existence, but on a struggle between the males for possession of the females; the result is not death to the unsuccessful competitor, but few or no offspring.” The evolutionary consequences of failing to obtain a mate are severe; they are equivalent to those of not having survived to adulthood: such individuals do not pass any of their genes to the next generation.

Darwin (1871) noted that competition for females takes two general forms: direct, male-male battles that involve either threats or actual fights and female choice, in which males attempt to induce females to accept them as mates. One common but unfortunate terminology distinguishes these as *intrasexual* and *intersexual* selection. Sexual selection, however, is *always* intrasexual; that is, individuals of one sex (usually males) compete with each other for access to individuals of the other sex (see West-Eberhard 1979, 1983). Regardless of the specific type of interaction, it is always true that individuals of one sex compete with each other; this intrasexual aspect gives sexual selection its particular characteristics in relation to natural selection, (see section “[Special Characteristics of Sexual Selection Versus Natural Selection](#)”).

Further, such terminology gives the idea that sexual selection processes are discrete and non-interacting. Separating the different types of sexual selection is not always feasible. Take, for example, the common cases in which males have battled not over females but over mating sites; when losing males are able to mate at least occasionally at other uncontested sites, then a female which mates at a contested site is exercising indirect choice in favor of fighting ability (Wiley and Poston 1996). Still another difficulty in classifying a situation occurs when alternative mating tactics are in play, so that some males gain access to females through combat or forceful copulations and others through courtship (Oliveira et al. 2008), or when a male succeeds in being accepted by a female, but his copulation is

prevented by another, dominant or “astute” male (see Thompson and Wrangham 2008; Painting and Holwell 2014). Another type of behavior that does not fit this terminology occurs when some males take advantage of the courtship of other males and gain acceptance by the courted females; an example would be the small male fish (“streakers”) that dump their sperm onto eggs that a larger male has induced the female to release into the water column to be fertilized (Oliveira et al. 2008).

As detailed below, the different types of sexual selection (i.e., contests of attractiveness, of threats, and of physical battles) can interact in complex ways. Analyzing the interaction between types of sexual selection on the evolution of sexually selected traits may provide important evolutionary insights for understanding details of this process (see the section on “[An Example of Conflict Between Types of Sexual Selection: The “Beautiful Weapons” of Fiddler Crabs](#)”).

This brief review begins by advocating that sexual selection be included in the broader evolutionary framework of social competition to highlight its peculiarities in relation to natural selection. The interactions between natural and sexual selection and their consequences for the evolution of traits under different types of sexual selection are discussed, with a focus on the exaggeration of sexual traits used in direct male-male battles and threats. Also, the ubiquitous existence of alternative tactics and rituals in male-male battles and threats is mentioned. Later, the different stages at which these male-male interactions occur (precopulatory, copulatory, and post-copulatory) are examined. Finally, the interaction between several types of sexual selection for shaping individual traits is analyzed using a specific case.

Before beginning, it is important to clear up possible problems for understanding direct male-male competition and confusions in terminology. Natural selection (differential survivorship that leads to differential reproduction) and sexual selection (differential reproduction) act most powerfully at the level of the individual, rather than at the level of the species. Therefore, it is not appropriate to consider traits observed in a species as

having evolved to “adapt the species” or “for the good of the species.” For example, it is inappropriate to perceive a mating strategy as being a strategy to favor the species; instead it is the outcome of evolutionary processes that favored in the past particular individual strategies under particular ecological scenarios. Polygamy, for instance, is not a strategy for achieving reproductive success for the species, but is instead the outcome of selective pressures acting on individuals.

Secondly, there are several possible payoffs to females for accepting some males but not others as mates. In some cases, the female gains access to resources controlled by the male (e.g., good oviposition sites); these are called “direct” benefits. In other cases, the female gains superior genes from the male for her offspring (“indirect” benefits, because the payoff is in the following rather than the current generation). There are two types of superiority. Some genes are associated with superior male survivorship traits (foraging ability, disease resistance, etc.), and in these cases there is selection on males to send courtship signals that correlate with these superior male qualities (the signals involve “indicator” traits) and on females to respond to such indicator stimuli. Another type of superiority in male genes concerns the male’s ability to elicit greater acceptance by females; the female gains by having sons that are better able to gain access to females in the next generation (“sexy sons”). In this case, there is no necessary correlation between the courtship signal and the male’s survivorship capabilities, so the signals are sometimes called “arbitrary” signals that pay off in producing sexy sons. Unfortunately, the terms “male quality” and “good genes” have often been used imprecisely, without clearly specifying which of these two contexts is in play. One final type of payoff for rejecting males is when the female avoids possible harm from the male that can compromise her own future survival or reproduction (e.g., avoiding a male who would induce her to produce his offspring at a suboptimal time for her); this has been called “chase away” selection (Holland and Rice 1998) and can lead to sexually antagonistic coevolution between the sexes (“SAC”).

Special Characteristics of Sexual Selection Versus Natural Selection

Darwin (1871) was the first to note the differences between sexual selection and natural selection. The contrasts between these justify including sexual selection under the wider evolutionary framework of *social competition*, which includes intraspecific competition for other resources besides mates (such as competition for social status, food, or parental care) (West-Eberhard 1979). Visualizing sexual selection as a specific case of social competition, in which members of one sex compete for members of the other sex as a critical resource in reproduction, provides an evolutionary framework for understanding several aspects of evolutionary importance (West-Eberhard 1983).

Sexual selection is relentless. Natural selection on some traits is intermittent according to variations in ecological conditions (e.g., resistance to cold, coping with food scarcity, or dealing with parasites) (West-Eberhard 1983); in contrast, the competition for mates nearly always occurs in every generation without fail. In addition, the payoffs for winning this competition can be huge in some contexts, such as social groups in which only one or a few individuals get most or all of the matings, while many individuals get few or none (West-Eberhard 1979). Another crucial aspect of sexual selection (and of social selection in general) is that success is always determined by comparisons. The ability of an individual to obtain fertilizations does not depend solely on his *absolute* capabilities, but most importantly on their *relation to* those of his competitors. Because the traits of a male's rivals change over evolutionary time, this relative nature of sexual selection tends to result in sustained evolution. A trait that is advantageous at one point in time (e.g., a novel design of a weapon or a signal) may currently yield a huge reproductive advantage because few other individuals have this trait. But in the future, when other males also have this trait, it may confer no advantage at all, and further innovations will be necessary to win out in the competition for females.

Because of this relative aspect of the process, the problems that sexual selection presents an

animal have no solution. Since the competitive environment changes with each improvement or modification made on a sexually selected trait, the race among rivals can be unending (West-Eberhard 1983). One form of this endless race is the “runaway process” in female choice, first identified by Ronald Fisher in his “Genetical Theory of Natural Selection,” in which male courtship traits and female preferences for these continually change (see Andersson 1994). This dynamic interaction contrasts strikingly with many ecological problems under natural selection, for which an adaptation can theoretically reach an optimum form and then undergo relatively little additional change.

In consequence, it is common for sexually selected traits to diverge more rapidly than naturally selected traits (West-Eberhard 1979, 1983). Furthermore, the sustained race between competitors can be at least partially decoupled from ecology, because the focus for sexual selection is the ability to obtain fertilizations over rivals, even if these come at certain expense for survivorship (see section “[Conflict Between Natural Selection and Different Types of Sexual Selection](#)” below).

Alternative Tactics

Even when certain sexually selected traits are superior to others (i.e., they tend to produce more offspring), it is common for some males of a species to have alternative traits that function to gain access to females using different tactics (e.g., by “sneaking” rather than battling for females). Alternative traits are especially frequent in male-male threats and battles (Blum and Blum 1979; Andersson 1994; Oliveira et al. 2008). The prevalence of such lower payoff tactics might seem difficult to explain, considering the frequently high intensity of sexual selection. Nevertheless, there are several reasons for actually expecting alternative tactics to be common.

The advantage of an alternative tactic can be appreciated by thinking about direct male-male competition from the point of view of a disadvantaged male (e.g., a small male who is unable to win physical fights with most of the other males in

the population). If such an individual is unable to obtain mates through the “main strategy” (such as defending a territory from other males), any other alternative, even one with relatively small pay-offs, is better than nothing. For example, in species in which the main strategy for males is to defend territories where females arrive to reproduce, individuals unable to win physical fights often sneak into the territories of dominant males to gain access to females there (sometimes disguising themselves morphologically or behaviorally as females or juveniles), or linger surreptitiously (like a “satellite”) at the edge to intercept the females as they arrive (Eberhard 1983; Oliveira et al. 2008). Occasionally, such alternative strategies yield matings.

In some species the alternative tactics by males simply represent different extremes along a continuous range of variation. Perhaps the easiest examples to document and understand occur in vertebrates in which the males, as they grow, gradually shift from one tactic to another (e.g., readiness to engage in physical fights) (Andersson 1994; Emlen 2014). Other alternatives are more discrete: some males utilize the main strategy, while others utilize an alternative

tactic throughout their lives. These “alternative reproductive tactics” or “ARTs” were reviewed recently by Oliveira et al. (2008) who distinguished “bourgeois” from alternative, “satellite” or “sneaker” male tactics. In species with morphological weapons, such a dichotomy is sometimes clearly marked between bourgeois males with large horns and satellite males without horns, with few if any males having intermediate-sized horns (Simmons et al. 1999; Emlen 2014) (Fig. 1).

Flexibility Versus Rigidity: Conditional Strategies Versus Evolutionarily Stable Strategies

The mechanisms by which two discrete male tactics are maintained in the same species have been the subject of much theoretical and empirical work (Oliveira et al. 2008). Two mechanisms that could explain how discrete alternative male tactics are maintained in the same population are the following. The two different male phenotypes could be the products of two different genotypes, and the selective advantages of the two alternative tactics could be balanced in such a way (i.e., frequency-dependent selection in which the rarest form is in advantage over the more common form)

Sexual Selection via Direct Male-Male Interactions,

Fig. 1 Distribution of horn length in relation to pronotum width in *Onthophagus taurus*, indicating a nonlinear relationship between these variables. Even though there is a continuous distribution on body size (pronotum width), there is a discontinuous distribution of horn length,

indicating a clear morphological dimorphism for this species. Horned morphs employ the main strategy (defending resources that attract females) and hornless morphs the alternative one (sneak copulations). Note that there are no small males with long horns and no large males with small horns (After Simmons et al. (1999), with permission)

that both sets of genes are maintained in the population. This possibility has been discussed in the large theoretical literature on evolutionarily stable strategies (“ESS theory”). A second possibility is that all males carry the genes for both phenotypes, but that any given male facultatively expresses one set or the other, depending on his particular circumstances (e.g., if he is large due to good larval nutrition as an immature, he expresses the fighting morph genes and represses the satellite morph genes). While the discussion continues to rage, the general consensus is that most alternative male mating strategies arise from facultative expression.

Perhaps the most obvious reason that phenotypic flexibility will generally be favored over ESS is that the ecological conditions that an individual experiences are often relatively unpredictable (for instance, being born in a lean vs. rich year or a rich or poor habitat). The social condition in which an individual is born can also be extremely variable (e.g., being the single male in a group vs. living in a group with several males). Any individual that is flexible and is able to adapt his phenotype to better suit the conditions he is called upon to deal with (e.g., having the ability to express the horned morph genes rather than the hornless morph genes when he is large) is likely to have an advantage over less flexible individuals who are condemned by their genes to utilize only one of the two options (see West-Eberhard 1979).

Consider, for example, a case where males fight for territories containing resources attractive to females. A fixed strategy of always fighting against challenging males would not be convenient for males that are small due to poor nutrition when they were young or for males that are challenged by more powerful opponents. Similarly, a fixed alternative strategy in which the male avoids interactions with other males and attempts to copulate only with females at the peripheries of territories would be disadvantageous if such a male is a good fighter because he is large and well nourished or when he encounters a territory with a relatively weak owner.

A second general line of evidence concerns the ESS supposition of equal reproductive success for

both types of male in the long run. The fact that large males choose to grow large weapons and adopt the main strategy rather than the alternative, weaponless strategy is evidence that the armed morph has greater reproductive success than the hornless morph. In essence, large males can choose either strategy, but consistently choose the main one, indicating that such strategy is likely to produce more offspring. Small males have no choice (they cannot be successful fighting males) and must make the best of a bad lot (e.g., Eberhard 1983).

One further general line of evidence suggesting that phenotypic flexibility is most common concerns the clear association in many (most) groups between larger male size and bourgeois male morphology and behavior (for instance, the tendency for large males to bear horns) (Oliveira et al. 2008). Because there is a strong correlation between an individual’s nutrition as it grows (strongly influenced by environmental factors such as season, year, habitat, etc.) and its final, adult size in many (most) species, one would expect that some individuals in a population would be large because of such nongenetic, environmentally determined factors. If there are separate genotypes for the bourgeois and alternate morphs, then some individuals with the satellite genotype will have, by chance, fed well as juveniles, and some with the bourgeois genotype will have fed poorly. The expectation is thus that there would be some large individuals in the population with no horns and some small individuals with horns. This expectation is not met (see Fig. 1) (also Eberhard and Gutiérrez 1991). Size and morph identity are tightly linked, something not expected under the ESS model.

Female Acceptance

There are several reasons to expect that females will not necessarily reject satellite males as mates (see Qvarnström and Forsgren 1998). First, even for females that are selecting males based on “good survivorship” genes, a male’s fighting ability is not necessarily reflective of his gene quality in this sense, as it will often be due to the particular environmental conditions he has experienced earlier in life (Simmons et al. 1999; Oliveira

et al. 2008; Emlen 2014). Second, for the reasons just given, a female can gain by having offspring that are flexible, and a male's flexibility can be signaled by his having of an alternative phenotype. Lastly, even when male phenotypes stem from genetic differences, it would be unlikely for alternate males to have inferior genes in relation to both survivorship (ecological adaptation) and reproduction (sexual selection), which is necessary to imply overall genetic inferiority that is not convenient for the female. Alternative strategies do not necessarily imply poor "survivorship genes," and main strategies are not always synonymous with good "survivorship genes."

Ubiquity of Alternative Strategies

The existence of trade-offs as a general rule in nature seems to always leave the door open for alternative strategies. For example, it is impossible for alpha male mandrills (*Mandrillus sphinx*) to have ever increasing numbers of females in their groups (thereby augmenting their matings), without paying the price of not being able to consort all fertile females at the same time. This leaves opportunities for other males to reproduce with at least some of them through alternate tactics such as behaving subordinately and mating in places that are not visible to alpha males (Setchell et al. 2005; Oliveira et al. 2008). Another trade-off concerns traits that provide advantages in postcopulatory interactions (e.g., large testes to transfer large ejaculates – see below) as opposed to traits that confer advantages in precopulatory interactions (e.g., Simmons et al. 1999; Simmons 2001).

As an example of trade-offs, consider male horned beetles of the genus *Onthophagus*; some males have large horns that they use to battle rivals by prying and blocking them. Fights take place at tunnel entrances that females dig under food resources (dung) with which they provision their offspring. Hornless males are nevertheless sometimes able to reproduce by digging tunnels that allow them to gain access to females deeper underground, in essence, by going around the horned males (Simmons et al. 1999). Large-horned males are less agile in maneuvering inside the tunnel and are inferior diggers because their

large horns get in the way. Small males that employ sneaking tactics invest more in traits associated with postcopulatory competition: they have larger testes and ejaculate more sperm than horned males (Simmons et al. 1999; Simmons 2001). The flexible nature of these alternatives has been documented by altering the amount of food provided to male larvae; well-fed larvae become large-horned adults, while poorly fed larvae become small, hornless adults (see Fig. 1). Other illustrations of alternative morph behavior occur in male giraffe and bottlebrush weevils. Larger males have longer rostrums which they use to defeat smaller males in fights that take place out in the open, where they then copulate with and guard females. However, very small males with shorter rostra are able to occasionally obtain copulations by sneaking close (often while the large male is distracted in a fight with a large rival) and hiding alongside or beneath the female (Eberhard 1983; Painting and Holwell 2014).

Because of the existence of trade-offs, the intense male-male competition that often leads to the exclusion of inferior males from females, and the variable, often unpredictable nature of ecological and social scenarios, alternative strategies are expected to be the norm in nature. This expectation is met, as alternative strategies in male contexts are common and taxonomically widespread (Andersson 1994; Oliveira et al. 2008). In ritualized threats and battles, the evolution of alternative strategies allows inferior fighters to salvage some reproduction in contexts where following the main strategy would have led to zero reproduction.

Why Male-Male Battles Are So Often Decided by Threats and "Honest" and "Dishonest" Signals

The use of threat displays to resolve battles can be advantageous to both the winner and the loser of an interaction. For the winner, avoiding a fight is probably generally cheaper in terms of energy expended and surely cheaper in terms of possible damage he might suffer. Giving up without a fight can also be selectively advantageous for the loser.

If an individual can correctly judge, on the basis of his rival's threat displays, that he could not win an actual fight, then ceding without fighting can save him time, energy, and possible physical injuries. It is striking that only very seldom does a winning male pursue his advantage and punish or attempt to kill a retreating rival. Presumably this is also because of likely costs and benefits: the low additional payoff if the loser is indeed leaving the vicinity, combined with the danger of being injured by a desperate rival trying to defend his life. Also, as will be detailed below, males can make mistakes when judging fighting abilities of their opponents, so sometimes it is not convenient for a winning male to risk a revaluation of his status if it was judged inaccurately by the losing male.

In contrast to courtship displays, evolution of threats to rival males are not expected to result in "arbitrary" signals like those in some female choice processes. This is because threat signals are thought to be periodically tested (possibly within an individual's lifetime and certainly on the evolutionary time scale) by actual combat as indicators of fighting ability (West-Eberhard 1979). A male will be favored if his threat displays are so convincing that he sometimes intimidates rivals who are superior fighters. But it is disadvantageous for a superior fighter to give up after being threatened by an inferior fighter: males are thus under selection to detect "dishonest" signals or bluffs by their rivals. In other words, a male's threat displays must be backed up by his ability to fight; a male cannot permanently afford to bluff concerning his physical ability to win fights, and overly ambitious bluffing males can be punished by losing costly fights. Aggressive displays are thus expected to give relatively, though not perfectly accurate ("honest") indications of each male's fighting abilities (or "resource holding potential" in the jargon). As will be described in the fiddler crab example (section "[An Example of Conflict Between Types of Sexual Selection: The 'Beautiful Weapons' of Fiddler Crabs](#)"), there is a certain amount of room for dishonesty, opening the door for intense selection on sensory and analytical capabilities.

These exchanges of information (truth and lies) are often accomplished during ritualized, gradually escalating threats that allow each individual to assess his opponent's fighting abilities. Usually the longest interchanges of threats, and the ones that escalate furthest, are those that occur between evenly matched, similarly sized individuals (Blum and Blum 1979; Andersson 1994; Emlen 2014). Contests between males that differ greatly in size, weapons, or endurance are usually settled rather quickly. The escalated nature of threats is likely a consequence of the males attempting to accurately judge their opponent's fighting abilities. For either male, an accurate judgment of an opponent's true fighting abilities (without incurring the costs of a full fight with a superior opponent) seems more likely when more information is available.

Accurate judgment of an opponent's fighting ability seems to be a major selective force in the evolution of weapon design. In several different evolutionary trajectories, weapons have evolved toward more complex or larger structures that reduced harm while allowing assessment of subtle differences in the fighting ability between opponents. In contrast, it appears that crude unimpressive weapons have a tendency to inflict more damage (Emlen 2008).

Exceptions to the advantages of ceding without a fight occur in situations in which a male has no alternative opportunity to reproduce. For instance, the wingless, heavily armed males of *Idarnes* fig gall wasps live in the internal cavity of a closed fig and fight with each other over the chance to mate with the females that emerge within the enclosed cavity. Females mate only once before they gnaw a tiny hole and leave the fig to search for another host to lay their eggs. In these wasps, males frequently fight to the death, using their giant mandibles and the powerful muscles in their oversized heads (Blum and Blum 1979). A given male lives and dies inside a single fig and cannot leave to find females elsewhere. Thus, for these males, there is no payoff from avoiding possible injuries or death by ceding to an opponent's threats; they have no other mating options. The numbers of deaths can be astronomical. William D. Hamilton (in Blum and Blum 1979) estimated that the number of

male wasps killed in battles in 1 year's crop of figs on a single large tree may be greater than all of the casualties of World War II. This mayhem contrasts with other species of fig wasps in the same trees in which the males have wings; they seldom engage in mortal combat and have the option of finding females elsewhere.

Conflict Between Natural Selection and Different Types of Sexual Selection

Although natural and sexual selection were recognized by Darwin as different processes, there exists the common misconception (in part due to the term "survival of the fittest") that those individuals that are better adapted to ecological conditions are also the ones that are better adapted for reproduction. Even though both natural and sexual selection refer to differential reproduction of individuals, it is important to bear in mind that the selective advantages that produce differences in reproduction can be different. Natural selection refers to higher reproduction due to higher ecological success (i.e., greater survival translates into more mating opportunities and greater ability to amass resources translates into production of more abundant or better endowed offspring). Sexual selection, on the other hand, argues that differential reproduction is due to differential success in fertilizing eggs (through contests of attractiveness, of threats, or of physical battles), even if this success comes at the expense of reduced survival. In sum, individuals that win in contests of attraction or direct combat are not necessarily the most adept at surviving. Also, individuals that are superior in many ecological aspects may achieve little or no reproduction if they are not superior in sexual contests.

The selective pressures that operate in natural versus sexual selection are different, so it is not unexpected that the two processes sometimes interfere with each other. Sexual selection theory posits that further exaggeration of sexually selected traits is often prevented by opposing natural selection (i.e., pressures for ecological adaptation) (Darwin 1871). Empirical, experimental tests for this aspect of the theory are surprisingly

scarce (see Andersson 1994; Kotiaho 2001). However, conflict between the processes is quite obvious in many cases. For example, predators and parasites are often strongly attracted to the sounds, pheromones, or visual signals produced by courting individuals (Andersson 1994). The large size of male lions, which makes them better fighters in competition for exclusive access to a band of females, makes them inferior hunters, and they depend on females to capture prey (which they then appropriate until they are satisfied). The same effect occurs in male courtship traits. Male swallows with longer tails attract more females, but longer tails have aerodynamic costs and make individuals less adept at catching profitable insect prey (see Andersson 1994; Kotiaho 2001). Similarly, the ornaments in the wings of predatory male damselflies (*Hetaerina americana*), which are used to threaten other males that invade their territories, render them more conspicuous to their prey and thus less adept at catching them (see Kotiaho 2001). In some groups, these costs are presumably large enough that males get rid of their sexually selected traits during the non-reproductive periods of the year. Cervids such as deer produce large, expensive heavy antlers that are shed after the reproductive season and regrown each year, presumably because of the higher costs associated with carrying them during the rest of the year (Emlen 2014).

The costly nature of some sexually selected traits makes it possible that they can be used as "indicator signals" to females, providing evidence that the male possesses superior survivorship genes because he is better able to pay these costs. It is also possible that rival males might use the costliness of the aggressive displays of a rival to judge his overall vigor. Many studies have shown that both courtship and threat displays are "costly" or energy demanding (e.g., see Andersson 1994; Kotiaho 2001). The consequence of this correlational link has been disputed, and Kotiaho (2001) argued that this does not imply that such activities have fitness costs (lowered survival and/or reproduction of the individual) because individuals may compensate somehow for this energy expenditure (e.g., by feeding more often). This may be true, but leaves

open the possibility for other ecological costs, such as the possibility that feeding per se involves risks from predators or from infections by disease-causing organisms. In any case, courtship and aggressive displays directed toward other males clearly require energy, and it is common for individuals in better body condition to engage in longer and more intense periods of display (see Andersson 1994).

Two additional types of cost are internal. One, which has received little attention until recently, results from possible competition over cell resources within the developing individual. For example, the production of elongated beetle horns during larval development is correlated with a reduced growth of nearby organs like the eyes and antennae (Emlen et al. 2005); stag beetles with larger mandibles have relatively smaller wings (Emlen 2014). This competition could be played out on two scales. At the level of an individual's development, depletion of resources in the vicinity of a growing organ may result in reduced growth of nearby organs. On the evolutionary time scale, the developmental program of a species needs to make adjustments of the distribution of the available resources in the most advantageous manner among different possible growth functions. This second evolutionary factor seems especially likely to be important, and indeed, some observations that have been cited to support the first (e.g., smaller wings in beetles with larger mandibles) have an alternative interpretation in this second context (larger males with larger mandibles may need to fly less between mating sites because they will less often be obliged to decamp after having failed to win a battle with another male).

A second "internal" cost is the general redirection of resources in the male from maintenance and survivorship functions to his sexually selected traits. Thus, for instance, it is common that relative investment in immune defenses against pathogens is reduced in males compared with females, especially during reproduction. For example, male baboons that maintain an alpha status within their group (and are thus able to constantly guard fertile females from rival males) have elevated concentrations of testosterone and stress

hormones that can suppress their immune system, in relation to beta males (Gesquiere et al. 2011). Similarly, in socially competitive environments, the more dominant and aggressive red morph of the Gouldian finch (*Erythrura gouldiae*) suffers from greater immunosuppression when compared to the more passive and submissive black morph (Pryke et al. 2007). A particularly dramatic case are the species of salmon fish which migrate from the ocean up to rivers and streams to spawn. The males undergo changes in the forms of their mouths which make them into weapons that are used in male-male battles, but make it impossible for the males to feed. In addition, the males' abilities to resist infections and repair incidental damage become reduced during the migration, and they often have numerous infections by the time they have reached the headwaters and are defending their spawning sites.

Finally, it is usually males who are exposed to greater ecological risks, simply because of their greater degree of movement while actively searching for females, who usually invest little in mate searching (Andersson 1994). A greater degree of movement results in higher mortality due to predation, as has been corroborated in studies that evaluate differential mortality between the sexes in a variety of organisms (see Andersson 1994). Another interesting possibility that has received little attention is that both searching and courting individuals may be more vulnerable to predation not only because they are more exposed to predators but because they are paying less attention to possible danger (see Dukas 2009). Reduced attentiveness may represent a danger for both sexes during courtship and copulation.

Exaggerated Traits and How to Measure Them

Male traits under sexual selection are often seemingly exorbitant or exaggerated (e.g., extravagant colors, elaborate songs, disproportionate morphologies, displays, etc.). Examples include both traits utilized to attract mates and to threaten and fight with rival males. For example, while female

beetles commonly lack traits that function for winning fights against conspecifics, male weaponry evolved several times in different beetle lineages, in the form of exaggerated mandibles, enlarged legs, or rigid horns (Fig. 2). Some weapons, such as beetle horns and earwig cerci, appear to be used only as weapons per se, without being previously displayed from a distance during threat behavior, but many other male armaments are also used in visual threat displays, as in deer and fiddler crabs, before being employed in physical battles (see Emlen 2014). However, some portions of weapons such as deer or insect horns allow “safe” interlocking that permits assessment of physical strength while reducing possible harm, and in these cases the distinction between threat displays and actual battle is blurred (Emlen 2008).

In morphology, the degree of exorbitance of structures that are involved in male agonistic interactions (say the length of a fiddler crab’s enlarged claw or of a beetle’s horn) can be expressed quantitatively, in terms of the relative size of such a structure when compared with the sizes of other body structures that are not under sexual selection and are indicators of overall body size (e.g., leg length, wing length, eye diameter, etc.). There is a very general trend for larger body size to be associated with disproportionately large weapons or threat devices, both in comparisons among individuals of the same species and in comparisons among different related species (Eberhard and Gutiérrez 1991). Stated in another way, the proportion of a male’s body that is dedicated to such sexually selected structures is

Sexual Selection via Direct Male-Male Interactions, Fig. 2 Horned beetles of the genus *Onthophagus* (Scarabaeidae), illustrating the diversity of form and location of horns (head and prothorax). Individuals shown are males unless otherwise specified (females with horns are presumed to use them to defend resources from other females). Top row: *O. xanthomerus* (female), *O. tersidorsis*, *O. gazella*, *O. xanthomerus*. Second row: *O. nuchicornis*, *O. sugillatus*, *O. rangifer*, *O. taurus*. Third row: *O. hecate*, *O. pentacanthus*, *O. capella*, *O. asperulus*.

Fourth row: *O. nigriventris*, *O. ferox*, *O. praecellens*. Bottom row: *O. sagittarius* (female), *O. haagi*, *O. sharpi*, *O. sagittarius*. The horns of *O. tersidorsis* and *O. rangifer* curve back over the dorsum, but are shown in an artificial vertical position to illustrate their form. The colors indicate different portions of the male where horns arise: black anterior portion of the head, yellow posterior portion of the head, red prothorax (Modified with permission from Emlen et al. (2005))

usually greater in larger individuals. A common way to quantify this exorbitance is to measure the slope of a log-log graph of weapon on body size; a slope of 1.0 would describe perfect proportionality between the two; many weapons have a slope >1.0 (often termed “positive allometry”). The trend for weapons to show positive allometry is so strong that some have mistakenly claimed that it is universal (see critiques by Bonduriansky 2007).

The selective explanation for positive allometry in weapons is probably related to the very general trend noted above for larger males to win when they fight smaller males (see Andersson 1994). A relatively large weapon can be a more effective threat device and also a more powerful weapon. In addition, while larger males can benefit from larger weapons with which they can outcompete more rivals (through effective intimidation or combat), smaller males may be unable to produce, carry, or effectively wield larger weapons. Also, as noted previously, smaller males are less likely to benefit long term from bluffing or exaggerating their combat abilities. Therefore, in relation to small males, large males might experience stronger selective pressures for increased weapon size; such a disparity could lead to positive allometry of male weapons in particular circumstances (Petrie 1988). Nevertheless, there are sometimes limits to the correlation of larger structures being more powerful weapons or functioning as more effective threat devices (see the section “An Example of Conflict Between Types of Sexual Selection: The “Beautiful Weapons” of Fiddler Crabs”).

Sexual Selection at Different Stages: Precopulatory, Copulatory, and Postcopulatory

Male-male competition does not end after mating; fertilization (or more accurately, offspring production), which is the ultimate goal of such competition, generally does not automatically occur once mating has begun. In the first place, ejaculation is often not immediate, and other males often attempt to disrupt copulations before sperm

transfer is complete. Physical displacement of copulating males has been documented in several vertebrate and invertebrate species (see Birkhead and Møller 1998). For instance, male *Pan troglodytes* interrupt the copulations of lower-ranking males by threatening them, but do not interrupt those of higher-ranking males (Tutin and McGinnis 1981); and they do so more often when females are more likely to be ovulating (Thompson and Wrangham 2008).

Even after sperm transfer occurs, fertilization is not guaranteed; males almost never transfer sperm directly onto the female's eggs in species with internal insemination, and females often mate with more than a single male during their lifetime (Eberhard 2009). A male's sperm may thus have to compete with sperm from previous or subsequent mates of the female. As a result of sexual selection, the male may utilize several different mechanisms to improve the chances that his own sperm is used for fertilization (Simmons 2001; Eberhard 2009). One simple technique is to dilute the sperm from previous (or subsequent) males with his own voluminous ejaculate, or by mating with the female repeatedly (he can thus win what has been called the “raffle” competition). Some birds perform “retaliatory copulations”, in which the male immediately copulates again with the female after he has seen her copulate with another male (Birkhead and Møller 1998). There is a positive correlation between the intensity of raffle competition and the relative size of testes in different species in several groups of vertebrates (see Birkhead and Møller 1998; Eberhard 2009).

A second male technique is to flush out or directly remove the sperm from previous males; this occurs, for instance, in several insect species such as dragonflies and beetles (Simmons 2001). Still another widespread tactic is to reduce the chances that the female will mate with additional males. Males accomplish this by defending her from other males (“mate guarding”) or by modifying her reproductive tract to make future copulations more difficult. Most often, this is accomplished by physically plugging her tract with a “sperm plug” or “copulatory plug.” This set of tactics is typically called “sperm

competition” and corresponds to the classic, direct male-male battles preceding copulation. Still other tactics used to win postcopulatory competition involve inducing the female to modify her postcopulatory physiology or behavior and correspond to classic, precopulatory female choice. There are more than 20 different known female responses that can bias the reproductive success of her different mates; among others, they include inducing the female to discard sperm from previous males, inducing the female not to discard or kill the sperm from the current male, inducing her not to mate with additional males, and inducing her to oviposit quickly before other males have a chance to find her (Eberhard 2009). Because the necessary female cooperation generally occurs hidden from view within the female’s body, this is commonly called “cryptic female choice” (see Eberhard 1996).

Copulatory plugs have been found in a variety of animal taxa, including vertebrates and invertebrates (Birkhead and Møller 1998; Simmons 2001; Uhl et al. 2010); they work in several ways. In some species they may serve as signals to discourage other males from attempting to mate with the female (Birkhead and Møller 1998; Simmons 2001). Some plugs in mammals and arthropods represent physical obstacles to the genitalia of subsequent males, as they are located at the entrance to the female or are deeper inside, blocking access to preferred sites for sperm deposition (Birkhead and Møller 1998; Uhl et al. 2010). Plugs sometimes involve subtle interactions between males and females. For instance, in some spiders, both male and female products are used to form the plug (e.g., Aisenberg et al. 2015); in squirrels, females sometimes immediately remove the plug when copulation ends and sometimes leave it in place. The use of plugs in these species may be the result of a combination of both direct male-male competition and indirect male competition via female choice. These interactions can be quite subtle. In the spider *Agelena limbata*, the openings of each of the female’s two insemination ducts are surrounded by a smooth cavity; smaller males are less able to fill this cavity sufficiently with plug material to prevent future males from achieving intromission,

while larger males more often fill it (see Eberhard 1996). By having this cavity, the female biases male-male competition via plugs in favor of larger males. There are some plugs, as in some primates, carnivores, spiders, and flies, that are not appropriately designed to exclude other males and may instead serve to reduce sperm loss or to stimulate the female (Birkhead and Møller 1998).

Another tactic which males use to avoid possible sperm competition from other males is to mate guard after insemination. In a variety of taxa, mate guarding has been shown to increase the male’s fertilization success by reducing the number of copulations by the female with other males or her future acceptance of sperm from other males (see Eberhard 1996; Simmons 2001; Setchell et al. 2005). Males can guard mated females by remaining coupled through genitalic contact (Blum and Blum 1979) or through non-genitalic contact (e.g., Painting and Holwell 2014), or by staying nearby (e.g., Setchell et al. 2005). Some males apparently guard mated females by mimicking them, thus diverting copulatory attempts from other males (see Simmons 2001). Males also guard females prior to copulation (e.g., before the female becomes sexually receptive); in some of these species, females mate only once or have short periods of receptivity or are difficult to find, and in this way, males increase their chances of future fertilizations (see Birkhead and Møller 1998).

There is often substantial intraspecific variation in several aspects of male sperm, including their general morphology, length, motility, and longevity (Eberhard 1996; Snook 2005). These sperm traits are probably the outcome of evolution under sperm competition and cryptic female choice (see Eberhard 1996, 2009). For example, in several vertebrates and invertebrates, males may produce sperm that can hook to each other and thus swim faster (i.e., sperm linking). Also, the evolution of parasperm (infertile sperm) in some groups, and their high abundance in ejaculates of some species, leads to suspicion of several possible functions of these under postcopulatory sexual selection. Similarly, the immense variety of seminal products, and their importance in achieving fertilization success, makes these targets of

postcopulatory sexual selection through sperm competition and cryptic female choice. After a long period in which sperm and seminal products were studied without reference to their likely functions under sexual selection, the functions of these structures are just beginning to be understood (Snook 2005; Eberhard 2009).

An Example of Conflict Between Types of Sexual Selection: The “Beautiful Weapons” of Fiddler Crabs

Fiddler crabs illustrate especially clearly some subtleties in the topics just discussed and offer a window on one particularly poorly understood aspect of the evolution of male weapons and threat devices. While it is well known that male weapons and threat devices tend to diverge especially rapidly over evolutionary time (see Fig. 3) (as is typical of sexually selected traits in general – e.g., Andersson 1994; Eberhard 2009), the immediate advantages of variant traits when they first

appear in a given lineage are much less well understood (Emlen et al. 2005; Dennenmoser and Christy 2013). It seems likely that the complex and probably unstable balances between the effects of different types of sexual selection (i.e., contests of attractiveness, threats, and physical fights) on such traits, which have been documented in special detail in fiddler crabs, have played important roles in the evolution of diversity.

While sexual selection favoring male weapons is often said to be balanced by one or more of the costs under natural selection that were discussed above, the situation in fiddler crabs is considerably more complicated (probably this complexity is typical, though less well documented, in many other species). There are complex webs of trade-offs because, as is also very often the case in other species, the fiddler crab’s weapon, his spectacular, sexually dimorphic fighting claw (Fig. 4) (in some species this claw constitutes up to one half or two thirds of the male’s body weight), is under several types of both natural and sexual selections. Sexual

Sexual Selection via Direct Male-Male Interactions, Fig. 3 Head and thoracic horns of males in the six known species of the *mirabilis* subgenus of *Onthophagus*, illustrating the small variations in horn shape and length in closely related species. Details with the same letter indicate comparable traits that vary among these species: *a* small

horn on anterior edge of prothorax, *b* long or short horn on anterior half of the prothorax, *c* long or short horn on anterior edge of head, *d* bump on head horn, *e* angle of head horn with rest of head, *f* indentation in lower surface of thoracic horn (Drawing after Génier and Howden 1999, with permission)

Sexual Selection via Direct Male-Male Interactions, Fig. 4 Fiddler crabs' beautiful weapons. (a) Male *Uca beebei* showing the oversized "major" claw used in displays and battles as well as the normal "minor" claw (on the left). Female claws resemble minor claws. Note also conspicuous coloration of the large claw (Photo

courtesy of John H. Christy). (b–d) Variation in major claw form (the claws are not shown all to the same scale). (b) The major claw of *U. argolicola* is short and robust (Modified with permission from Swanson et al. (2013)). (c) Regenerated and (d) original major claws of *U. annulipes* (Modified with permission from Backwell et al. (2000))

selection acts on the male's claw to attract females, to intimidate rival males in prefight interactions, and to accomplish both offensive and defensive functions that enable him to win physical fights. In addition, it has naturally selected consequences, attracting the attention of some predators, but defending against others, and it may also aid in thermoregulation. Several types of interactions between these kinds of selection, and their possible roles in the generation of evolutionary diversity, are illustrated particularly clearly in the fiddler crab genus *Uca*.

First, the stage must be set. Males of two especially well-studied species, *U. beebei* and *U. terpsichores*, fight over burrows that they dig in sandy beaches and mud flats. The burrows are costly to build, but they are valuable in attracting females as mates, and most agonistic interactions between males are tightly linked to both their burrows and their enlarged claws. Males display these claws prominently when courting females and threatening other males. Larger males tend to have larger claws, and those with larger claws tend to win both threat displays and physical fights. When one male *U. terpsichores* approaches another who is defending a burrow, each male waves his enlarged claw back and forth and up

and down rapidly. When males differ substantially in size, these claw-waving threat displays (sometimes accompanied by pushing) usually result in one male (usually the smaller) surrendering and leaving the burrow without a fight. Some displays, however, fail to resolve the conflict, and the males then fight each other physically by interlacing their enlarged claws jerkily; then each pinches the enlarged claw of the other. The claws are packed with muscle, and the pinches are so powerful that they sometimes puncture or crush the cuticle of the opponent (the scars from this damage signal the exact sites where a male's claw has been squeezed by rivals and thus where his cuticle has had to resist such squeezes).

A longer claw is a more effective display device, both for intimidating other males and for courting females; but it also tends to be an inferior weapon because of its reduced mechanical advantage (longer claws deliver weaker pinches with their tips). This conflict between the signaling and the physical properties of claws (between "beauty" and "brawn") has been elegantly confronted in *U. beebei* and *U. terpsichores* by subtle changes in claw morphology: subapical teeth on the claw deliver the squeezes in fights, rather than the claw tips. In larger individuals (and

in the same individual as he grows), these teeth are relatively more distant from the tip, thus reducing or eliminating the loss of pinching force (brawn) produced by longer claws without sacrificing the intimidating effects of their length (“beauty”).

There are still other axes of variation in sexual selection on claw morphology. Animal weapons often have defensive as well as offensive properties; in these crabs the cuticle of the claw must be thick not only in the regions where squeezing muscles are anchored but also in the areas that receive pinches from rivals to avoid being damaged. There is also another axis of trade-offs regarding the thickness of the claw’s cuticle. Lighter claws are better for signaling females (and males), because males can wave them more vigorously and for longer compared with heavier claws. In contrast, heavier claws make better weapons. Comparing pinching forces across 21 *Uca* species, most had claws that were just heavy enough to resist being crushed in a fight (Swanson et al. 2013). A comparable type of defensive structure are the basal tines on the antlers of stags which intercept stabbing movements by the antlers of rival males (Emlen 2014).

What would happen if males attempted to falsify signals about their fighting abilities and pretended to be better than they really were? Just such prevarications occur sometimes in fiddler crabs. When a predator seizes a male’s enlarged claw, he causes it to break off while the crab attempts to scramble to safety. Such an “autotomized” male, when he reaches the following molt, does not have enough resources to regenerate an entire claw of the size appropriate for his body size. One “truthful” option would be to make a smallish claw that is only as large as he is capable of filling with muscle and providing it with an appropriately thick cuticle; such a small claw would be relatively unattractive for females and also relatively ineffective in intimidating rival males (even those of comparable body size). The opposite “liar” extreme would be to regenerate a partially empty claw that showed a length typical for a male of his body size, but that had less muscle mass and hence could not pinch as forcefully or had a thinner cuticle that was less able to resist the pinches of rival males.

Several species of *Uca* regenerate such “dishonest” claws (see Fig. 4). In *U. annulipes* and *U. mjoebergi*, neither other males nor females were able to visually distinguish such a regenerated “dishonest” claw in threats or courtship (Backwell et al. 2000; Lailvaux et al. 2009). Regenerated males compensated for their inferior weapons by avoiding the possibility that interactions with rival males would escalate from threats to physical fights (Backwell et al. 2000). In effect, regenerated males “parasitize” the responses of other individuals to their dishonest claws, which evolved in response to the general honesty of the morphology of unregenerated males. Males in nature can thus be confronted with a mixture of more and less honest signals from rivals; and the frequencies of liars are sometimes alarming (up to 44 % of natural populations of male *U. annulipes* have regenerated claws – Backwell et al. 2000). Selection on male criteria for ceding without fighting is likely to vary as percentages like these change.

General Lessons

When selective forces act in opposition to each other, variation in the timing, intensity, and direction of selection can produce a range of possible outcomes. These well-studied fiddler crabs confirm this prediction. They enable one to appreciate the possible importance of several different factors at once and thus to begin to sense the likely importance of the balances between multiple selective pressures in the evolution of male traits under sexual selection. Trade-offs and adjustments occur in several dimensions: (A) a design adjustment to allow both improved signaling and fighting by larger males, (B) a trade-off between advantages resulting from the offensive versus defensive capabilities of a weapon, (C) a possible trade-off in signaling males as opposed to females (signal traits which increase the signal’s effectiveness as a threat when directed to other males may not be maximally effective in courting females), and (D) the uncertainty that males may experience in relation to the signals of rivals regarding their fighting abilities. This last problem could result in

relentless coevolutionary races between male cognitive abilities to perceive and distinguish honest from dishonest signals and to produce ever more effective dishonest signals.

A complex web such as this, composed of interacting factors whose importance relative to each other is likely to vary over both ecological and evolutionary time, is also likely to be affected by still other factors such as the population density (greater advantage in giving up without a fight in populations where alternative opportunities are more likely), the male's age (e.g., self-defense becomes less important as the male becomes older and has less future reproduction to lose), the male's size (brawn adaptations will be more important if he is larger), and his previous experience (e.g., opportunity to learn to distinguish honesty from dishonesty). Such a gumbo of interacting variables seems a recipe for variation in selective pressures and could thus offer an explanation for the rapid diversification of male weapons and threatening devices in different closely related lineages (see Fig. 3).

General Significance for Psychobiology

There are several general lessons to be learned from the fiddler crabs. In the first place, the same traits can function both as weapons and as display devices, and these displays can be directed at males as well as females. Probably the majority of male weapons are also used as display devices in agonistic interactions. Secondly, the aspects of a structure that make it a more effective weapon are not necessarily those that make it a more effective signal to intimidate a rival male. This disconnect means that there may be a dynamic balance between selection on a signaling male to overemphasize (or lie about) the fighting prowess correlated with his weapon and selection on the receiving male to evaluate this correlation correctly and not be fooled by bluffs. Conflicting pressures of this sort will also be in operation in the evolution of other, "pure" signaling traits such as territorial songs, even though in this case the correlation between the male's signal and his fighting ability is more indirect. Periodically,

males will be called upon to back up their threats with physical prowess. As illustrated in the fiddler crabs, this balance of selective pressures on a single trait is likely to be subtle and dynamic, with occasional "errors" made in both directions. Such errors could lead to the development of new traits and evolutionary divergence in the weapons.

While the authors do not know of examples of similarly elaborate trade-offs in sexual traits involved in direct male-male conflicts, in which strategy and counterstrategy have been worked out in elegance similar to that of these morphological studies, it is reasonable to assume that this lack is because of the greater intrinsic difficulties of quantifying behavioral details and contexts with comparable precision, rather than because behavior does not lend itself to subtle conditional strategies. In fact, of course an animal's behavior is much more plastic than its morphology and can be adjusted almost instantaneously to that of a rival (perhaps because of selection on these strategies and counterstrategies). This expectation of rich complexity, plus the basic, well-established theoretical background of sexual selection theory and the clear trend for sexual selection to produce rapid, divergent evolution, makes exploration of the psychobiology of direct male-male interactions under sexual selection an attractive subject for further study.

Conclusion

The evolutionary consequences of the competition between members of one sex (usually males) to gain access to the opposite sex can be better understood as a form of social selection. This intrasexual competition starts before copulation and often continues during and even after copulation. The mechanisms and processes of sperm competition, cryptic female choice, and sexually antagonistic coevolution are just beginning to be understood. Intrasexual competition can take many forms (threats, battles, courtship), so that different sexual selection pressures may interact in complex ways to shape the design of sexually-selected traits; these complex interactions may lead to the evolution of diversity in weapons.

Most weapons probably also function as threat devices besides their obvious use in combat. There are theoretical reasons why to expect approximate (though not perfect) honesty in these signals. Similarly, there are evolutionary reasons to expect that alternative reproductive tactics are a general norm in nature. The intense nature of social competition, along with the need to accurately detect honest and dishonest signals between rivals, may pose never-ending cognitive challenges to the members of the competing sex.

Sexual Signaling During Ovulation

Robert P. Burriss

Faculty of Psychology, University of Basel,

Synonyms

Attractiveness; Concealed ovulation; Fertility

Definition

Women may signal or inadvertently communicate to others their fertility status, which varies over their menstrual cycle.

Introduction

The likelihood that a single act of sexual intercourse will lead to conception varies over a woman's menstrual cycle, peaking in the days preceding ovulation (during estrus, sensu Thornhill and Gangestad 2008). Some species of primate advertise fertility status with conspicuous signals, such as bright pink sexual swellings. Women do not conspicuously advertise their fertility, but neither is estrus completely concealed. In an oft-cited study, Miller et al. (2007) asked professional exotic dancers to keep a record of their nightly tip earnings for 2 months. The dancers received about US\$67 per hour when they were near ovulation,

but only US\$52 at less fertile times of the month. Why did patrons give larger tips to ovulating dancers? Research has shown that women's appearance, body odor, voice, and behavior vary over the cycle and that men and women are able to detect these changes in others (reviewed in Haselton and Gildersleeve 2015).

Attractiveness and Cycle

There is converging evidence that women are more attractive during estrus. When women's voices are recorded at multiple times over the cycle, recordings made when women are most fertile are rated as more attractive by men and women, possibly because of the effects of estrogen on the larynx. Both men and women prefer the natural body odors of women who are in the high rather than the low fertility phase of their cycle. Women rate t-shirts worn by women near ovulation as smelling more pleasant; men rate them as more pleasant and more sexy. The effects of the cycle on voice pitch are relatively weak; effects on body odor are stronger (Haselton and Gildersleeve 2011).

Photographs of women's faces taken near ovulation are rated significantly more attractive than photographs of the same woman taken later in the cycle, when fertility is lower (Roberts et al. 2004). Recent research suggests that this effect can partially be explained by changes in face shape, possibly attributable to head posture. Women's faces, like those of some nonhuman primates, may also vary cyclically in color, although this change may not be perceivable.

Women move differently over the cycle. In one study, women were videotaped dancing to pop music and men rated those dances for attractiveness. Dances were more attractive when performed at high fertility (Fink et al. 2012). Evidence that women's gait varies cyclically is mixed.

Voluntary Signals?

Indiscriminate signaling of fertility status is unlikely to be adaptive, as such signals would

attract the attention of undesirable as well as desirable men (and possibly rival women). But there may be instances when it is advantageous for women to behave in a manner that effectively signals fertility. The biologist Bernard Campbell (1974) has suggested that researchers might find "voluntary signaling by the female replacing the involuntary physiological signals of estrus." His prediction has been borne out by research on women's clothing preferences. Durante et al. (2008) had women draw pictures of outfits they would choose to wear to an evening social event. Women in their fertile phase drew outfits that others rated as more revealing and sexy. Further research shows that women also wear more red and pink clothing – which men find attractive – when fertile, especially when the weather is inclement and revealing clothing is not an option (Tracy and Beall 2014). Women also spend more time on personal grooming near ovulation.

This is not to say that women consciously signal their fertility status through clothing and other forms of ornamentation, but psychological changes associated with the cycle (including a greater desire for men other than the primary partner during estrus) may motivate behaviors that are perceivable by others and therefore convey information about a woman's fertility.

Clothing and other behavioral cues to ovulation can also be deployed facultatively, when it is advantageous for a woman to signal her sexual interest toward desired mates. When women are fertile they are more interested in short-term relationships, and one way of expressing this interest is to flirt. But fertile women do not flirt with every man they encounter, instead directing their proceptive behavior toward men who are attractive (Cantú et al. 2014).

Conclusion

Women's fertility status is not as easily discernible as it is among females of some other primate species. It may be beneficial to conceal estrus, both to limit unwanted advances from males who seek to monopolize female sexuality and to

reduce harassment from rival females. If this is true, why do women signal their fertility at all? The *leaky cues hypothesis* proposes that women do not benefit from advertising their fertility status to others, but that it is maladaptive to suppress all cues to estrus as this would have an adverse impact on fertility. At the same time, the selection pressure on men to detect any physical or behavioral cues to ovulation is likely strong, because men who are able to direct their mating efforts toward women who are at peak fertility will be more reproductively successful. What appear to be signals of estrus are cues that are too costly to conceal entirely and which third parties are adapted to detect.

Sexual Size Dimorphism

Robert Cox

Department of Biology, University of Virginia,
Charlottesville, VA, USA

Synonyms

[Sexual dimorphism in body size](#)

Definition

A characteristic difference in body size (height, length, mass) between males and females of a population or species.

Introduction

Sex differences in adult body size are common throughout the animal kingdom and are generally thought to arise from the joint influences of sexual selection, which often (but not always) favors

large body size in males, and fecundity selection, which often (but not always) favors large size in females. In humans, as in other organisms, these inferences are based in large part on comparative studies of correlated evolutionary patterns between sexual dimorphism and proxies for the intensity of sexual or fecundity selection across entire evolutionary lineages, such as primates or mammals. The evolution of sexual size dimorphism is also constrained by the shared genome of a species, which can give rise to intralocus sexual conflict over body size and other traits. Adaptive hypotheses for sexual size dimorphism and the dynamics of intralocus sexual conflict are discussed in a general evolutionary framework that applies to diverse animal taxa, with specific reference to humans and related primates and mammals.

Sexual Size Dimorphism

Sexual size dimorphism is ubiquitous throughout the animal kingdom and often varies considerably in its direction (i.e., which sex is larger) and magnitude (i.e., by how much), even at the level of family, genus, or species (Fairbairn et al. 2007). Body size is determined by a combination of genetic and environmental factors that interactively influence growth and development throughout an organism's lifetime. In turn, body size influences most aspects of an organism's anatomy, physiology, ecology, and life history. This complexity of both cause and consequence is one reason why it has proven challenging to develop a general theory capable of predicting the direction and magnitude of sexual size dimorphism for a given species, even within particular lineages such as mammals or primates (Fairbairn et al. 2007; Fairbairn 2013). An additional layer of complexity stems from the fact that males and females share the vast majority of their genomes, including many of the genes that influence growth, development, and body size (Badyaev 2002). Consequently, the magnitude of sexual size dimorphism should reflect not only the balance of selective pressures acting on the body sizes of males and females but also the extent to which a shared genome constrains the sexes from

Sexual Size Dimorphism, Fig. 1 Differential equilibrium model for sexual size dimorphism (modified from Blanckenhorn 2007). Covariance between body size and components of relative fitness gives rise to fecundity selection (component of relative fitness = fecundity), viability selection (probability of survival), and sexual selection (mating and fertilization success). The balance of these selective forces sets the equilibrium body size for each sex. The observed level of sexual size dimorphism is determined by the offset in these equilibria and the counteracting effects of genetic constraints, as illustrated by a positive correlation between mean body sizes of brothers and sisters, as commonly observed in contemporary human populations. The direction and strength of each type of selection are purely hypothetical in this figure

evolving independently in response to these selective pressures (Fig. 1) (Gordon 2006; Cox and Calsbeek 2009).

Evolutionary Hypotheses for Sexual Size Dimorphism

Most evolutionary hypotheses for sexual size dimorphism focus on the ultimate, selective advantages of larger or smaller size in one or both sexes. In general, larger body size tends to facilitate the production of more and/or larger

eggs or embryos, the avoidance of predators, and success in competition for mates and other resources, but it can also reduce agility, require greater skeletal support, and demand a larger overall energy budget and increased offspring provisioning. Despite this potential for body size to influence fitness in a variety of ways, it is broadly accepted that sexual selection (on male size) and fecundity selection (on female size) are the two primary factors responsible for the evolution of sexual size dimorphism across diverse animal lineages (Cox et al. 2003; Fairbairn et al. 2007). Sexual selection arises from variance in mating success (which is often, but not always, greater in males than in females) and tends to favor large size when males compete aggressively for mates and small size when males engage in agile displays or scramble competition for widely dispersed females (Fairbairn 2013). The latter scenario may explain some of the most extreme cases of sexual size dimorphism in the animal kingdom, in which tiny “dwarf males” persist as little more than accessory sperm donors for females that exceed them by orders of magnitude in body size, a situation that has evolved independently in deep-sea anglerfish, pelagic octopuses, bone-eating marine worms, and shell-dwelling barnacles (Fairbairn 2013). Fecundity selection arises from variance in the number of offspring produced and will favor large females under conditions where larger size provides more space for developing eggs and embryos or larger nutrient and energy reserves with which to provide a greater number of offspring. The near ubiquity of this condition is believed to be the primary reason why females are larger than males in the vast majority of animal taxa, which runs counter to the more familiar pattern of male-biased sexual size dimorphism in humans and many other mammals (Fairbairn 2013).

Sexual and fecundity selection act in concert on males and females, so the level of sexual size dimorphism for a given species is predicted to reflect a “differential equilibrium” between the strength and direction of sexual selection on male size versus that of fecundity selection on female size (Fig. 1) (Blanckenhorn 2007). Natural selection acting through differential survival also

influences the equilibrium body size in each sex and is often conceptualized as a force that counteracts sexual and/or fecundity selection for ever-increasing body size (Blanckenhorn 2000). However, natural selection for viability also favors large body size in many situations and may sometimes generate or reinforce sexual size dimorphism by acting in opposite directions on each sex (Cox and Calsbeek 2010). Natural selection is also the primary force invoked by “ecological hypotheses” proposing that sexual dimorphism reflects the independent adaptation of males and females to different aspects of their shared environment, often as a means of adaptively reducing intraspecific competition by allowing the sexes to exploit different resources (Shine 1989). Ecological hypotheses are difficult to test because divergence in resource use is likely often a consequence of sexual size dimorphism arising for other reasons. Moreover, many species exhibit pronounced sex differences in body size without apparent differences in resource use or differences in size opposite those predicted by resource partitioning (Shine 1989).

Sexual Size Dimorphism in Humans and Other Primates

Contemporary humans are sexually dimorphic in a number of morphological traits related to shape and size. Relative to females, males generally have broader shoulders and wider rib cages, narrower pelvis, and longer and heavier bones with larger areas for muscle attachment (Plavcan 2012). As adults, human males average 7% taller and 15% heavier than females (Gustafsson and Lindenfors 2004). Although much of this dimorphism emerges gradually during development, minor sex differences in body size are present at birth and can be traced back as early as the first trimester of pregnancy (Bukowski et al. 2007). This modest degree of sexual size dimorphism falls toward the low end of dimorphism across nonhuman primates, which ranges from a few species in which females are equivalent to or slightly larger than males (e.g., gibbons) to extremes in which males average more than

twice the mass of females (e.g., gorillas) (Plavcan 2012). Across mammalian orders, male-biased sexual size dimorphism is the rule, particularly in diprotodonts (kangaroos), rodents, carnivores, ungulates, and primates, while sexual monomorphism or modest female-biased size dimorphism typifies chiropterans (bats) and lagomorphs (rabbits) (Lindenfors et al. 2007). Viewing *Homo sapiens* against the backdrop of diversity throughout the animal kingdom, Fairbairn (2013) concluded that humans “show a fairly typical pattern of sexual dimorphism for a large, terrestrial mammal, with males maturing later and at a slightly larger size than females, and female shape being adapted for gestation, birth, and parental care (p. 191).”

Hypotheses invoking sexual selection and fecundity selection as the causes of sexual size dimorphism can be tested by taking the phylogenetic relationships among a group of species into account and then asking whether evolutionary changes in dimorphism are associated with changes in variables that reflect the level of sexual or fecundity selection (Cox et al. 2003; Fairbairn et al. 2007). Across mammals and specifically within primates, evolutionary changes in categorical proxies for the strength of sexual selection, such as mating system (e.g., polyandry/monogamy < polygynandry < polygyny), explain a large and significant amount of the evolutionary change in sexual size dimorphism (Lindenfors et al. 2007; Plavcan 2012). Among nonhuman anthropoid primates, the occurrence of agonistic contest competition among males is the best predictor of sexual dimorphism in body size and in the size of the canine teeth, which are often displayed and used as weapons in these contests (Plavcan 2012). Nonetheless, simple categorical predictors such as mating system and the presence or absence of agonistic male-male contests leave much of the statistical variation in sexual size dimorphism across primates unexplained, raising the question of whether this indicates a need for more precise and quantitative estimates of sexual selection or consideration of additional selective pressures.

The influence of fecundity selection on sexual size dimorphism in primates and other mammals

has been frequently debated, with some evidence supporting the counterintuitive hypothesis that fecundity selection actually favors smaller body size as a means of increasing lifetime fecundity through earlier and more frequent reproduction involving less energy expenditure per reproductive episode (Lindenfors et al. 2002; Lindenfors et al. 2007; Plavcan 2012). Though reproductive rate and lifetime fecundity tend to correlate negatively with mean body size across species (Lindenfors 2002; Lindenfors et al. 2007), intra-specific correlations between individual size and reproductive rate tend to be weak or absent in most primates, suggesting that current fecundity selection does not act strongly on female body size (Gordon 2006). Though sexual selection via both male and female mate choice has received considerable attention in the evolutionary psychology literature, and may often act on dimensions of body size and shape in both sexes (Pawlowski et al. 2000; Courtiol et al. 2010; Mautz et al. 2013), there is little direct evidence to confirm a role of mate choice in shaping sexual size dimorphism (Puts 2010). Consequently, the modest male-biased sexual size dimorphism exhibited by humans is generally interpreted as a consequence of historical patterns of sexual selection favoring large male size in relation to agonistic competition for mates, though factors such as fecundity selection, viability selection, and mate choice acting on one or both sexes may have also played a role in establishing the precise magnitude of this dimorphism.

Intralocus Sexual Conflict over Body Size

When selection on a given trait acts in opposite directions in males and females, it is said to be sexually antagonistic. When a trait subject to sexually antagonistic selection is influenced by many of the same underlying genes in each sex, then the trait and its underlying genes are said to be subject to intralocus sexual conflict (Bonduriansky and Chenoweth 2009; Cox and Calsbeek 2009). Because any gene located on an autosome will spend roughly half of its time in males and half of its time in females, genes that are detrimental

when expressed in males can be maintained in a population because they are beneficial to females and vice versa (Stearns et al. 2012). When manifest across numerous traits and underlying genes, this genome-wide conflict can reduce the overall fitness of a population by constraining males and females from evolving toward their respective fitness optima for the phenotypes under selection. Intralocus sexual conflict can therefore be viewed as a specific (and nearly ubiquitous) case of the more general evolutionary problem of producing two different phenotypes from what is predominantly the same underlying genome (Pennell and Morrow 2013). Over long evolutionary time-scales, this genomic conflict can be resolved (at least partially) through a variety of mechanisms that facilitate the sex-specific inheritance (e.g., sex chromosomes) and expression (e.g., hormonal regulation of transcription) of shared genes, thereby permitting the evolution of sexually dimorphic phenotypes (Stewart et al. 2010). Indeed, the fact that so many traits are sexually dimorphic indicates that, given sufficient time, these genetic constraints can be overcome. Nonetheless, a variety of theoretical considerations and empirical results suggest that a complete and lasting resolution to intralocus sexual conflict is unlikely (Bedhomme and Chippindale 2007; Mank et al. 2008; Pennell and Morrow 2013). This conclusion is consistent with the observation that many highly dimorphic phenotypes are still subject to ongoing sexually antagonistic selection favoring even greater sexual dimorphism (Cox and Calsbeek 2009).

In haplorhine primates, evolutionary patterns in body size suggest that sexual selection for larger body size in males has, via a correlated evolutionary response, displaced females of polygynous species from their optimal size for lifetime fecundity by necessitating greater postpartum investment in larger offspring (Lindenfors 2002). In human populations, body size or stature is heritable (Silventoinen 2003), and its genetic covariance between males and females is estimated to be quite high, meaning that selection on body size in one sex should produce a highly correlated evolutionary response in the opposite sex (Rogers and Mukherjee 1992). Based on these

genetic estimates, the rate of evolution in the mean body size of a human population in response to selection should be more than 60 times greater than the rate of evolution for sexual dimorphism in mean body size (Rogers and Mukherjee 1992). These estimates suggest that the prolonged displacement of one or both sexes from their respective fitness optima is a likely consequence of sexually antagonistic selection on body size.

Longitudinal studies of lifetime fitness (number of children) in sibling pairs from contemporary human populations provide direct evidence for intralocus sexual conflict over body size (Stulp et al. 2012). Whereas sisters have relatively greater lifetime reproductive success than their brothers in sibling pairs of shorter height (the optimal height for female reproductive success), brothers have relatively greater reproductive success than their sisters in sibling pairs of average or slightly above average height (the optimal height for male reproductive success). Similar conclusions have been reached from studies simultaneously quantifying sexually antagonistic selection and predicting evolutionary responses based on the quantitative genetic architecture of body size and a variety of correlated physiological traits in a contemporary human population (Stearns et al. 2012). These studies collectively suggest that sex differences in human body size are subject to ongoing sexual conflict that maintains genes with deleterious effects in one sex due to their beneficial effects in the opposite sex.

Conclusion

Human males average 7% taller and 15% more massive than females as adults. These size differences are toward the low end, but not atypical, relative to other primates and large terrestrial mammals. As in other species, this sexual size dimorphism is generally thought to reflect a history of sexual selection for a larger and more robust physique in males due to agonistic contests over mating opportunities. However, fecundity selection, viability selection, and sexual selection via mate choice have likely also shaped the evolution of body size in both sexes. Body size is

moderately heritable in many contemporary human populations and also strongly genetically correlated between males and females, which inhibits the evolution of sexual size dimorphism and leads to intralocus sexual conflict over body size and related traits.

Sexual Socialization

Laura Vandenbosch

University of Leuven, Leuven, Belgium

Definition

Adolescents' development of attitudes, norms, beliefs and behaviors regarding sexuality in response to socialization agents.

Introduction

During adolescence, sexual processes take up a central position. The acquisition of a positive sexual identity is considered to be a key developmental task for adolescents (Tolman and McClelland 2011) and can be described as the

process of “understanding [one’s] own sexual orientation as well as sexual needs and values, preferences for sexual activities, partner characteristics, and modes of sexual expression (Worthington et al. 2002, p. 512).” Modern evolutionary theory explains that this process is driven by biological stimuli, such as pubertal maturation and sexual hormones (Steinberg 2005), and is influenced by environmental factors as environmental flexibility helps to meet biological goals (Belsky et al. 1991).

The most significant environmental factors are so-called sexual socialization agents (i.e., parents, peers, and media) that guide adolescents' development of attitudes, norms, beliefs, and behaviors regarding sexuality (Tolman and McClelland 2011; Ward 2003). Social cognitive theory explains that these agents (e.g., peers or media characters) may model sexual and relational behavior that can be observed and adopted by adolescents, especially if the behavior is rewarded (Bandura 1999). In addition, these agents inform adolescents on attitudes, norms, and beliefs towards sexuality that are considered as favorable (Bandura 1999).

Importantly, sexual socialization agents differ in the *type* of messages they promote as being favorable. More precisely, the literature distinguishes positive and negative messages. Positive messages are messages that socialize adolescents towards a positive sexuality defined as “sexuality that is consensual, honest, mutually pleasurable, non-exploitative, and protected against unintended pregnancy and sexually transmitted diseases (STDs)” (Ward et al. 2006, p. 59). When messages deviate from this description of a positive sexuality, they are regarded as negative or risky in the literature.

Because of the substantial impact that the development of a sexual identity has on adolescents' current, but also their future well-being, research has studied extensively the relationships between sexual socialization agents and adolescent sexual maturation (Tolman and McClelland 2011). Over the years, three (related) areas of research have been developed that each focus on a key socialization agent: (1) parents, (2) peers, and (3) media.

Parents

Parents are considered to be the prime socialization influences in children's life (Belsky et al. 1991). During childhood, parents model and structure children's early understandings of sexual relations and the roles of women and men in sexual interactions (Belsky et al. 1991; Inazu and Fox 1980). The influence of parents in sexual maturation persists in adolescence (Tolman and McClelland 2011), but takes on different shapes. Adolescents increasingly start to explore their own sexuality and talk with their parents about sexuality (Tolman and McClelland 2011), though, at the same time, they start to rely less on their parents in general (Fulgini and Eccles 1993). Adolescents identify their parents as sources of information on physical health risks and responsibilities that come with sexual behavior (Epstein and Ward 2007). The importance of developing a sexual agentic self-concept, sexual desires, and respect for sexual minorities is in general less likely to be covered in the sexual socialization messages of parents (Epstein and Ward 2007).

The inherent, hyper personal nature of sexuality is a burden on parent-child interactions regarding sex and may explain why topics, such as masturbation, are rarely covered in parental conversations about sex (Diiorio et al. 2003). Such conversations are characterized by feelings of discomfort, shame, and guilt, especially on the side of the adolescent (Epstein and Ward 2007; Ogle et al. 2008). Mothers seem to handle these (somewhat) uncomfortable situations better than fathers as they talk more often to their sons and daughters about sexuality (Bleakley et al. 2009; Diiorio et al. 2003).

In general, research suggests that parental sexual messages socialize adolescents towards attitudes and behaviors that are characterized by a focus on (health) responsibilities and a less supportive view of an early initiation of sexual behaviors (Bleakley et al. 2009; Inazu and Fox 1980; L'Engle and Jackson 2008), though inconsistent findings have also emerged (Diiorio et al. 2003). In this view, the relationship between parental socialization and sexually protective behaviors has been found to vary according to factors,

such as the timing of the parental message (before or after an adolescent's sexual debut) and the communication style of the parent (open vs. restrictive) (Miller et al. 1998; Whitaker et al. 1999).

Also the literature warns that stereotypical beliefs about sexual gender roles seem to affect parental sexual socialization (Lottes and Kuriloff 1994). Such stereotypical beliefs are believed to be rooted in different inherited strategies for reproductive success by men and women (Eagly and Wood 1999). These strategies encourage promiscuous sexual behavior among men (for instance, because men face the risk of raising children whom they are not biologically bounded to) and long-term committed relationships among women (for instance, because male partners can help to protect the family) (Eagly and Wood 1999). In line with these strategies, socialization research has noticed that especially girls are socialized towards restrictive sexual attitudes and behavior, while boys are sometimes even supported to gain (early) sexual experience by parent-sex communication (Diiorio et al. 2003; Lottes and Kuriloff 1994).

Overall, the literature indicates that parents can play an important role in postponing early sexual behavior and preventing a sexual risk trajectory (L'Engle and Jackson 2008). At the same time, the literature also suggests that the diversity of topics covered in parent-child conversations is sometimes limited (Epstein and Ward 2007; Ogle et al. 2008) and that factors, such as gender stereotypes and communication style, partly determine the strength and direction that the influence of parental sexual socialization messages takes on.

Peers

While the importance of parents decreases during adolescence, peers gradually take on a more central role in adolescents' life (Fulgini and Eccles 1993). In general, adolescents heavily rely on peers in their everyday life and in particular for providing them with sexual information (Bleakley et al. 2009). Peer conversations about sex are

common and focus on a variety of themes, such as exchanging their (emerging) experiences with sex and beliefs about (successful) sexual relationships (Epstein and Ward 2007). Such conversations are likely to signal which sexual attitudes and behaviors are considered as normative in the peer group and seem to evoke pressure to comply to these peer standards.

While parents are known to rather support sexual abstinence in the literature, peers tend to socialize adolescents towards more positive liberal attitudes regarding sex and to support the initiation of (risky) sexual behavior (Bleakley et al. 2009; Epstein and Ward 2007). This is demonstrated by research showing that adolescents become more popular when they gain sexual experience (Prinstein et al. 2003; Sieving et al. 2006). Moreover, research has reported that peer factors, such as perceived peer approval of teen sex, perceived peer sexual behavior, and general sexual communication with friends, increase adolescents' chances to initiate sexual intercourse and oral sex (L'Engle and Jackson 2008; Prinstein et al. 2003).

(Perceived) social rewards from peers thus seem to accelerate adolescents' sexual trajectory. However, null findings have also been found (Frison et al. 2015; Prinstein et al. 2003). In line with the literature explaining inconsistent results on parental sexual socialization, peer socialization processes may also differ for boys and girls. Stereotypical norms suggest girls should have some sexual experience, but cannot be seen as sexually promiscuous (Lottes and Kuriloff 1994), while boys consistently gain social status when having more sexual experience (Lottes and Kuriloff 1994). These stereotypes seem to shape peer sexual socialization as adolescent boys indicate to experience more peer pressure to initiate sexual activities at an early age than girls (Potard et al. 2008). Accordingly, adolescents also believe that male peers are more sexually experienced than female peers (Frison et al. 2015).

Apart from these gender differences, other characteristics of peer networks, such as the religious background of one's close peers or their socio-economic status, may further determine the sexual norms that are promoted (Tolman and

McClelland 2011). Moreover, the sexual norms promoted by one peer group may include some messages that are considered as risky for sexual maturation but, at the same time, also other messages that are protective for adolescent health. For instance, one study reported that the peer network of French adolescents socialized them towards positive attitudes towards contraception. The same peer group also promoted an early sexual debut, though (Potard et al. 2008).

Together, the literature suggests that the peer group socializes adolescents into a wide variety of themes regarding sexuality and (in general) tends to support adolescents to engage in (early) sexual behavior. Such pressure is intertwined with traditional gender roles. Some literature also points to the importance of peer characteristics, such as the type of friends, to determine whether the peer network functions as a positive versus negative sexual socialization agent. Moreover, the influence of a particular peer group on adolescent sexuality may be positive or negative depending on the area of sexuality that is being considered. More knowledge is needed to further explain under which conditions peers may positively affect adolescent sexuality. This knowledge is particularly relevant as peers may perhaps have the most significant influence on adolescent sexuality.

Media

Adolescents indicate to spend a considerable amount of their daily time with using media (Vandenbosch 2013). In the media popular among adolescents, sexual messages are prevalent (Ward 2003). To illustrate, an average adolescent will be exposed to approximately 35,328 sexual television messages when he/she reaches adulthood (Vandenbosch 2013). Media scholars argue that entertainment media (e.g., television and magazines), but also pornographic media are particularly appealing as sexual information sources because of their anonymous nature, prevalent and (in case of pornography "highly") explicit references to sex, and power to engage users in stories (Brown et al. 2005; Peter and Valkenburg 2016;

Ward 2003). As for social media, their features can provide an online playground to experiment with one's sexual identity, but also to observe how other peers express their sexuality (e.g., through sexy selfies and sexting) (Ringrose 2009).

In line with this reasoning, entertainment, social, and pornographic media have been identified as valuable sexual information sources by adolescents (Bleakley et al. 2009; Ringrose 2009; Vandenbosch et al. 2018). These media can contain positive or negative information about sexuality. More precisely, some television shows and (online) magazines discuss potential risks and responsibilities that come with engaging in sexual activities (Aubrey 2004; Hust et al. 2008). Most literature has, however, warned for media's role as a risky sexual socialization agent (Brown et al. 2005) and in particular their promotion of the so-called *Reductionist Script of Instant Gratification* (Vandenbosch 2013). In this script, sexuality is predominantly focused on receiving sexual satisfaction which is inherently linked to sexual attractiveness and stereotypical gender roles. Romance is reduced to a sexual, hedonistic game with differential play styles for boys and girls (i.e., sexual double standard), though both are expected to comply with narrowly defined appearance ideals (i.e., being thin or muscular) (Vandenbosch 2013).

Numerous studies have examined whether the components of this Reductionist Script of Instant Gratification in popular media lead to adversarial consequences for adolescent sexual maturation. For the associations between mainstream entertainment (i.e., television and magazines) and social media, and adolescent sexuality, inconsistent results have led to question the media's role as a socialization agent (van Oosten et al. 2018). As for pornographic media, consistent support has emerged for the links between sexually explicit media use and adolescents' recreational attitudes towards sex, views of women as sex objects, and increased (risky) sexual behavior (Peter and Valkenburg 2016; Vandenbosch 2013).

Importantly, research across media genres agrees that inconsistent findings have resulted from poor attention to the conditions that explain when and how adolescents may be affected by

sexual media content (Vandenbosch 2013). As such, the role of differential susceptibility factors and response states in sexual media effects (Peter and Valkenburg 2016; Vandenbosch 2013; Ward 2003) has been more systematically studied during the last decade. This research identified groups of adolescents who not only have an increased likelihood of being affected by exposure to the Reductionist Script of Instant Gratification in popular media, but also those who may benefit from media exposure (Vandenbosch 2013). Important differential susceptibility factors refer to developmental traits (e.g., age, puberty), social factors (e.g., family environment), and dispositional characteristics (e.g., sensation seeking, hyper gender identity) (Peter and Valkenburg 2016; Ward et al., 2013). Studies on response states have shown that sexual media effects often occur "indirectly" through processes, such as excitative (e.g., arousal) or cognitive (perceived utility of media content) responses (Peter and Valkenburg 2016; Vandenbosch et al. 2018).

Together, the literature has described the affordances that media may offer as a sexual socialization agent for adolescents and the risks associated with the adoption of the information on sexuality that is (frequently) promoted in (popular) media. Current research seems to agree that media exposure may affect adolescent sexuality, but that these sexual media effects depend on differential susceptibility factor and (partly) develop through indirect processes (i.e., response states).

Reflections to Consider in Future Research

This review indicated that there is a substantial body of research on sexual socialization agents. Past research especially aimed to understand under which conditions parents function as protective sexual socialization agents, and peers and media as negative sexual socialization agents. The current overview of the literature has led to several critical gaps in the literature. These gaps suggest, at least, four major directions for future research.

First, research has mainly investigated sexuality from a reproductive health perspective

focusing on sexual (risk) behavior and liberal sexual attitudes. The definition of a positive sexuality however points at different areas of sexuality including sexual desire, sexual intimacy, and respect towards sexual minorities (Ward et al. 2006). Little is known about which roles peers, parents, and media may play in these areas with some notable exceptions, e.g., pornography effects on sexual satisfaction (Peter and Valkenburg 2016) and peer effects on homophobic behavior (Birkett and Espelage 2015).

Second, the general assumption that parents versus peers and media are, respectively, protective and risky sexual socialization agents seems to prevent research from exploring whether these roles are not univocal and potentially may differ in regard of the considered area of sexuality and the type of adolescent. For instance, the representation of homosexual individuals in popular media is considered favorable for their visibility in the society, but the stereotypes surrounding their representation in media content is evaluated as problematic (Calzo and Ward 2009). Given the pros and cons attached to the televised messages on homosexuality, it is not surprising that research suggests some groups develop more positive attitudes towards homosexuality, while other groups seem to become less tolerant towards homosexuality when watching more television (Calzo and Ward 2009). More precisely, women and less religious individuals have more favorable attitudes towards homosexuality in general. As a result, television exposure may cause them to develop less positive attitudes towards homosexuality. The reverse is true for men and more religious individuals, though. These groups appear to be less tolerant towards homosexuality in general, but seem to be more tolerant when watching more television (Calzo and Ward 2009). Overall, more knowledge to explain under which conditions different socialization agents have a protective versus risky influence in various areas of sexuality is needed. Such insights will help to reveal the complex role that agents have in different groups of adolescents.

Third, the dynamic, reciprocal nature of the sexual socialization process is rarely examined in research. Theoretical models explaining how

(sexual) socialization processes manifest themselves underline a dynamic interaction between an individual and his/her environment (Bandura 1999). Individual or environmental traits will affect how the individual responds to sexual socialization messages. In turn, these responses will shape the future messages an individual receives from a socialization agent (Bandura 1999). For instance, a mother may first socialize her daughter towards the adoption of rather liberal sexual attitudes. Because of the sensation seeking personality of the daughter, she may respond to this socialization by engaging in risky sexual activities. When the mother observes this behavior, she may (temporarily) change her approach and socialize her daughter towards more restrictive sexual attitudes and behavior. In this example, the socialization agent thus adapted her approach in response to the child's behavior. Although theory predicts such dynamic processes in socialization approaches, empirical research is largely lacking. Such research may provide useful insights in the conditions that shape different socialization influences, though. Longitudinal or dyadic daily experience studies may be especially warranted to examine such dynamic processes. Such studies are overall rather rare in the field of sexual socialization research.

Fourth, research has mainly studied the influence of socialization agents as separate entities, while (1) multiple socialization agents may simultaneously affect adolescent sexual maturation and (2) socialization agents may affect each other, which, in turn, may influence adolescents sexuality. First, a scarce set of studies has untangled how the influence of a sexual socialization agent can be strengthened, weakened, or changed by the influence of another socialization agent on adolescent sexuality. These studies have shown that the (protective) influence of parents may interact with the (risky) influence of media and peers (Vandenbosch and Eggermont 2011a; Whitaker and Miller 2000). For instance, when adolescents discuss sexual subjects with their parents more frequently, peer pressure to have sex tends to relate less strongly to adolescents' sexual behavior (van de Bongardt et al. 2014; Whitaker and Miller 2000).

Second, limited research has examined models that propose interactions with other socialization agents as fundamental processes to explain the links between a socialization agent and adolescent sexuality. In this research, media use (e.g., increased exposure to reality TV) and parental interactions (e.g., lower parental support) were found to affect peer processes (e.g., increased sexual communication with peers, having more sexually active peer friends). In turn, these peer factors have been related to adolescents' (advanced) sexual experiences (Vandenbosch and Eggermont 2011b; Ward 2002; Whitbeck et al. 1993).

Such research supports that the influence of sexual socialization agents cannot be considered as working independently from each other, but necessitates an interactive approach to truly unravel how sexual socialization processes influence adolescents' emerging sexualities.

Conclusion

Together, it has become clear that the role of sexual socialization agents needs to be considered by taking into account the complexity that surrounds the process of developing a sexual identity and in which multiple factors play a role. This review will hopefully help future research in revealing the interplay between different sexual socialization agents, different types of adolescents, and their sexual maturation processes.

Sexual Stigmatization

Panteá Farvid

Auckland University of Technology,
Auckland, New Zealand

Synonyms

Sexism; Sexual injustice; The sexual double standard

Definition

A form of sexism where men and women are judged differently for engaging in the same sexual behavior (with women carrying the stigma).

Introduction

Sexual stigmatization refers to a sexual double standard within sexuality, where men and women engaging in the same sexual conduct are judged differently – with women carrying the stigma. The idea comes from traditional concepts of heterosexuality, where male and female sexuality are understood differently. Here, open and expressive female sexuality is disparaged, whereas desirous male sexuality is sanctioned and celebrated. Although the norms of Western heterosexuality are shifting – the sexual double standard remains powerful in shaping heterosexuality in various domains. In this entry, the history, norms, and current context of the sexual double standard in the West are covered.

The Sexual Double Standard

The sexual double standard is a form of sexism within heterosexuality where the same sexual behavior enacted by men and women are judged differently. For example, men who have many sexual partners are positively deemed as “studs” and women negatively judged as “sluts,” “skanks,” or “whores” (Farvid et al. 2017, p. 544–545, see also: Crawford and Popp 2003; Jackson and Cram 2003; Lai and Hynie 2010; Lees 1993; Ringrose et al. 2013; Ronen 2010; Hess et al. 2015). One of the explanations typically given for this phenomenon is that men are raised to value sexual experience, where women are taught to focus on emotional aspects of sex and committed relationships. Furthermore, the reason the sexual double standard is seen as a sexual injustice is because men are given more sexual freedom while women are socially stigmatized for engaging in the same behavior and hence have their sexual expression curtailed (Lyons et al. 2011).

The sexual double standard creates a narrow ideal of male sexuality as well – requiring men to demonstrate overt sexual interest and prowess (Kettrey 2016). Such ideals stem from traditional

concepts of male and female sexuality as identified by the seminal work of Wendy Hollway and Michelle Fine. Hollway’s (1984, 1989) work was able to showcase a widespread cultural acceptance that male sexuality is biologically needy and uncontrollable, whereas Fine’s (1988) work elucidated how sexual desire and pleasure is absent when it comes to female sexuality. These dominant cultural tropes, or sex-role stereotyping, position men as active sexual agents and women as passive and responsive, creating a social and cultural climate where something like the sexual double standard can exist (Milnes 2010).

Historical Context

The expression of the sexual double standard has varied across time. For example, in the Victorian Era women were desexualized and the enjoyment of sex was seen as exclusively a male domain (Gordon 1994). There were different gendered ideas of sexual purity – where men engaging in adultery or prostitution were dealt with more leniently socially and legally than women. Women were required to be chaste and moral and only engage in sex to bear offsprings, otherwise they were “fallen” women who had sex outside of marriage, for pleasure, or for money. Even being out in public without a chaperon might relegate a woman to the status of “prostitute.”

The work of early sexologists such as Sigmund Freud and Richard von Krafft-Ebing in the late 1800s and early 1900s created a different model of sexuality, focused on science (description and categorization) rather than religion (morality and regulation) (Farvid 2012). This, along with increasing discussion and display of sexuality allowed for more liberalizing attitudes about sex to gather traction. The “roaring twenties,” for example, is referred to by some historians as revolutionary in relation to sex (Dean 1996). By the 1960s and 1970s, this had culminated in fully fledged sexual permissiveness in various sectors of Western society (Allyn 2000).

Permissive sexuality situates both men and women as desiring agents who can have consenting sex in any context: “anything goes, as long as no one gets hurt” (Braun et al. 2003, p. 238). Based on this model, sex is positioned as inherently good and the right of men *and* women to enjoy. While permissive attitudes toward sex spread and pre-marital sex were on the rise (Reiss 1960, 1967), the experience and outcomes of permissiveness were often very different for men and women in this period. For example, women still carried the stigma of being considered “loose” or “easy” as well as having to deal with contraception and unwanted pregnancies (Campbell 1980).

At the turn of the twenty-first century, norms about sexuality and men’s and women’s sexual behavior are arguably at their most liberal, particularly when it comes to female sexuality. As Farvid and Braun (2006) noted, we are very much in the midst of a “pro-sex” cultural climate, characterized by a sexualization (Evans et al. 2010) and pornification of culture (Mulholland 2015) and a mediatization of sexuality (Couldry and Hepp 2016). For example, an active, desiring, and pleasure-focused female sexuality is depicted in women’s magazines, online and in popular television shows (e.g., *Sex and the City*, *Girls*, *Broad City*) and movies (i.e., *How to be Single*, *Trainwreck*). Yet, sexuality continues to be a tenuous terrain for heterosexual women – who must now walk a tightrope between being an over-sexed slut or an uptight prude. Women need to embody a sexually “liberated,” desiring and active sexuality, while at the same time avoiding activities or behaviors that may tarnish their sexual reputation.

Early Sexual Double Standard Research

Seminal work on the sexual double standard was carried out by sociologist Ira Reiss in the 1950s and 1960s. He examined attitudes related to “pre-marital sexual intercourse” – where it was typically seen as wrong for women but acceptable or even desired for men (Reiss 1956, 1960, 1967). Towards the end of the 1960s, he identified a loosening of the premarital sexual standard,

where pre-marital sexual activity was accepted among both men and women, as long as it was in the context of an affectionate or loving relationship (Reiss 1967). Indeed research in the 1970s indicated that premarital sex was no longer subjected to a sexual double standard (King et al. 1977) – but the sexual double standard did not disappear.

Research in the 1980s and 1990s produced mixed results – but clearly indicated a shift in how the sexual double standard manifested and in relation to what sorts of behaviors. In their review of this material (between 1981–2001), Crawford and Popp (2003) noted that although sexual attitudes and norms had become more egalitarian – men and women were still judged differently with regards to specific sexual *behaviors*. For example, women were judged more harshly for having sex at a younger age, for having sex outside of committed relationships (casual sex, infidelity), and for having sex with many partners (Crawford and Popp 2003). Furthermore, carrying condoms, wearing certain types of clothing, or acting flirtatious or in a sexual manner could also garner negative reactions and labeling (Hillier et al. 1998; Lees 1993). In addition, women were judged more harshly for being the initiators of sex or dates, and if there were negative outcomes in a dating or sexual situation, women were seen as more culpable if they were initiators.

Hence, there was a more subtle “fine line” that girls/women may cross when it came to the sexual double standard in this period but concerns about negative sexual reputation were evident (Kitzinger 1995). Furthermore, the sexual double standard, concerns regarding negative social judgments or a sexual reputation, had negative health outcomes. There were more negative individual, emotional, and social consequences for women (for example, women were less likely to carry condoms or initiating condom use due to the concern of being deemed a “slut”).

More Recent Work

From the early 2000s until now, a plethora of diverse work on the sexual double standard has continued to be published (Bordini and Sperb

2013). Such work has been able to map the changing nature of the sexual double standard, examining the complex and contradictory ways it manifests in the contemporary context. Before discussing this work – it is useful to outline the different theoretical approaches typically utilized in such research.

Theoretical Frameworks

There are three major theoretical clusters used to make sense of the sexual double standard. These are the biological/evolutionary approach (Buss 1994), sociocultural/social role theories (Gagnon and Simon 1973), and cognitive social learning (Bandura 1986). Biological theories tend to stem from evolutionary perspectives and posit that the sexual double standard stems from adaptive survival tendencies related to reproductive success. Men need only to invest a small amount in the biological aspect of reproduction, and it is women who carry and give birth to a child. Here women become more selective about how much sex they have and with which partners, as they prefer long-term mates who will help raise any off-spring that may be born as a result of sexual activity. Whereas men can be less discriminate and may seek to spread their seeds far and wide to garner as many offsprings as possible. Although this theory seems plausible, direct scientific evidence that captures prehistoric drives is impossible to gather. Attitudes and behaviors explained by this approach are also explainable by the following theories.

Sociocultural/social role theories tend to better contextualize why the sexual double standard might occur by highlighting dominant constructions of male and female sexuality and the way in which society expects different behaviors from men and women. For example, the sexual double standard is perpetuated by socially produced gender ideals or *scripts* that determine the norms regarding how men and women ought to behave, sexually (Greene and Faulkner 2005; Lai and Hynie 2010). Gender roles and gender role expectations play a huge role in how both actors and observers interpret and respond to the sexual behavior of men and women (Zaikman and Marks 2017). We respond more positively to behaviors that reinforce our gender specific

expectations, and vice versa. In this context, female sexuality is monitored and scrutinized in a way that male sexuality is not, because of the restrictive ways female sexuality has been constructed. Feminist and gender theorists have used this approach to highlight the sexist ways dominant heterosexuality operates, with a view to challenging and disrupting the sexual double standard (see Farvid et al. 2017).

Cognitive social learning theory posits that the sexual double standard exists because behaviors that are gender-role specific are reinforced within our society, and those that are inconsistent are punished (Zaikman and Marks 2017). Although similar to behavioral theories, there is an element of modeling in this theory. It posits that individuals imitate the behaviors of others that result in social rewards, avoiding those that result in social punishments – however subtle or overt (Zaikman and Marks 2017). For example, boys and men are usually evaluated positively for having many sexual encounters and are judged harshly if they fail to express overt sexual success yet, the situation is reversed for girls and women (Bordini and Sperb 2013). Among teenagers, the popularity of girls decreases with the number of sexual partners she has (regardless whether this occurs within the context of a relationship or not), while the popularity of boys increases with the more sexual partners they have (Kreager and Staff 2009).

Although various researchers utilize these theories separately, Zaikman and Marks (2017) argue that each theory mostly likely has some predictive power when explaining the sexual double standard:

First, evolutionary theory is a likely explanation for the origins of the traditional double standard. Second, social role theory can explain more proximate manifestations of the sexual double standard through considering the influence of context, culture, and historical era. Finally, cognitive social learning theory can explain the manner in which the SDS is perpetuated (p. 418).

Current Research

The prevalence of a sexual double standard continues to be documented, both in quantitative

(Greene and Faulkner 2005; Lyons et al. 2011; Marks and Fraley 2006; Zaikman et al. 2016) and qualitative investigations (Farvid et al. 2017; Jackson and Cram 2003; Marks and Farley 2007; Reid et al. 2011). Although the nature and expression of the sexual double standard has shifted, at its core, the sexual double standard invokes traditional discourses of heterosexuality, such as the Madonna/whore binary (virtuous versus promiscuous), to negatively construct women's desire for, and participation in what is socially, culturally, or morally defined as "too much" sex (Ussher 1989). Research in the last decade has garnered some interesting insights into the morphing, yet persistent, nature of the sexual double standard, which affects women's and men's expression of sexuality differently.

For example, women, but not men, still report more shame and guilt after having casual sex due to the way this behavior can still garner negative judgment from others towards them (Campbell 2008; Littleton et al. 2009). Female university students also report engaging in less hookups or coital casual sex to avoid garnering a negative sexual reputation or pejorative labeling (Hamilton and Armstrong 2009).

Although there have been shifts in sexual norms, and pre-marital sex and sex in relationships is now acceptable for women, showing explicit sexual desire and engaging in "unconventional" sexual behaviors that are considered out of the norm for feminine sexuality can still be risky for women (Bordini and Sperb 2013). For example, women are judged more harshly than men for engaging in threesomes, having multiple sexual partners, and having sex with a much younger partner (Kreager and Staff 2009). Sexting is another arena where the sexual double standard is identified. Research indicates that teenage girls who are asked to produce specific forms of sexual display by teenage boys face moral condemnation and "slut shaming" (by peers, parents and adults) (Ringrose et al. 2013).

"Slut shaming" is new phrase that names (and critiques) the act of openly criticizing people, usually girls and women, for transgressing the boundaries of what is perceived appropriate conduct in relation to sexuality. Recently, a "reverse"

sexual double standard has also been identified – where men are judged more harshly for engaging in overtly sexual conduct (Thompson et al. 2017), as well as a backlash to individuals who openly "slut shame" (Papp et al. 2015). Such shift indicates that stereotypical and open expressions of the sexual double standard are becoming less socially acceptable. Yet, the sexual double standard has definitely not disappeared.

For example, in the liberated context of Norwegian high school graduation celebration, researchers have found that while overt slut shaming was rare among young adults, women who were perceived as engaging in sex and casual sex in specific ways were subjected to subtle moral judgments (Fjær et al. 2015). In this context, a slut was always positioned as "other" and seen as someone who did not value physical and sexual safety or lacked self-control when it came to sex. Hence the sexual double standard was still identified, but the boundaries of what constituted problematic sexual conduct, for women, had shifted.

Similarly, research by Farvid et al. (2017) with women who explicitly identified as engaging in and enjoying casual sex identified that:

At the outset, casual sex was framed as being pleasurable and acceptable for women to engage in and a sexual double standard in relation to casual sex was directly challenged by all the women. . . The threat of garnering a negative sexual reputation however, was linked to the women's silence around their casual sex experiences and overt displays of sexuality. . . [yet] certain types of casual sex display were talked about as not acceptable and rightly procuring someone (although, never them) a negative sexual reputation (p. 556).

Women who engage in what was considered "too much" casual sex (e.g., every night or every weekend) and for the "wrong" reasons (e.g., feel better about themselves or to get attention, or address emotional or psychological issues) were stigmatized in this context. We know that not only men but women evaluate other women based on the sexual double standard (Zaikman and Marks 2014). A phenomena called "defensive othering" has been used to explain how women who endorse the sexual double standard do so to distance themselves from what is perceived as a lower status women; conversely, men who endorse a reverse

sexual double standard distance themselves from the dominant group (Kettrey 2016).

The sexual double standard has been identified as operating on multiple layers. For example, there is a difference between identifying a societal level sexual double standard, a larger peer group double standard, and the standards by which women themselves buy into or adhere to (Farvid et al. 2017). In one study, teenage girls identified a societal and school-level prevalence of the sexual double standard, but support from close friends and peers was a buffer to such ideals being fully accepted or affecting the girls negatively (Lyons et al. 2011).

Other studies of adult women and men have indicated that an active and desiring sexuality for women is, overall, supported or validated (Farvid 2014; Reid et al. 2011), yet explanations of men's and women's behavior in specific contexts can produce double standards (Beres and Farvid 2010). For example, in a study looking at a hookup scenario followed by a "sexless" date indicated that while men and women were not judged differently for engaging in a hookup or desiring a date, the explanations given for the sexless date were imbued with a double standard (Reid et al. 2011). Women were described as seeking to remain chaste (on the date) in order to regain any loss of their sexual reputation (during the one-night stand), and the men were seen as going on a date in order to make the woman feel better about the hookup (i.e., a "pity date") (Reid et al. 2011).

While some research indicates that the sexual double standard is being openly challenged (Allen 2003; Farvid et al. 2017; Jackson and Cram 2003; Milnes 2010), deep analyses indicate that it has not fully lost its grip on how we understand, interpret, and judge sexual behavior. Beyond general sexism, the sexual double still results in more negative outcomes for women. Girls and women spend a considerable amount of energy negotiating the risks of expressing an unfettered sexuality, with reports of worry, anxiety, and shame in this context (Ringrose et al. 2013). Furthermore, women who endorse the sexual double standard are more likely to refrain from sex altogether and leave sexual safety measures in the hands of men

(Danube et al. 2016). Lastly, the sexual double standard still affects how women judge other women (Farvid et al. 2017; Lyons et al. 2011). The sexual double standard is hard to escape, even for individuals who are aware and critical of it (Farvid et al. 2017).

Conclusion

The sexual double standard represents a gender-specific dilemma when it comes to sexual conduct, which affects girls and women much more negatively. The expression and contours of the sexual double standard have varied historically, with liberalizing attitudes towards sex and female sexuality softening its expression. Yet, as this entry has demonstrated, while the boundaries of the sexual double standard have shifted, it remains a powerful force in contemporary culture, in shaping male and female sexuality, as well as how sexual behavior by men and women is understood and interpreted. It seems that a radical reworking of heterosexuality is still needed if the sexual double standard is to ever lose traction.

Intersexual relations; Mating strategies

Definition

Sexual strategies theory (SST) is a middle-level evolutionary theory of mating strategies that both males and females adopt under different circumstances. It differs from previous theories in that it includes multiple motives each individual can have, such as short-term versus long-term mating, as well as when and why different motives would be predominant.

Introduction

Sexual strategies theory (SST) posits that humans have evolved a complex menu of mating strategies, that some of these mating adaptations are tethered to the temporal dimension of mating, and that although some mating adaptations are similar in women and men, some differ profoundly between the sexes (Buss and Schmitt 1993). Before describing the major premises, predictions, and empirical tests of SST, it is useful to briefly describe theories of mating prior to its articulation.

Previous theories typically posited singular mating motives, such as a quest for similarity, a search for complementarity, or the desire for equity. These theories had five major limitations that SST sought to rectify: (1) each posited a single mating motive, rendering them extremely simplistic; (2) all failed to explain why humans would be motivated by the singular drives; (3) all failed to specify the domains or contexts in which people sought similarity, complementarity, or equity, a degree of generality that precluded any domain-specific predictions; (4) all assumed that mating psychology was identical for men and women, precluding any sex-differentiated predictions; and (5) none specified functions, the adaptive problems solved by its central mating motive, thus divorcing mating psychology from any evolutionary anchoring. SST sought to rectify these limitations.

Nothing is closer to the central engine of the evolutionary process – differential reproductive success – than mating. Those who fail to select and attract a mate fail to become ancestors. To an evolutionary psychologist, it would defy scientific logic if evolution by selection had failed to forge a powerful set of adaptations surrounding mate selection, as it has in all known sexually reproducing species. SST posits, therefore, that whatever mating motives humans have exist because they solved adaptive problems that contributed directly or indirectly to successful reproduction over the long course of human evolutionary history.

The Two Major Axes of Sexual Strategies Theory

The two major axes of SST are temporal duration of mating (ranging from short-term casual sexual encounters to long-term committed mating relations) and biological sex (male, female). Biological sex is critical because humans differ in their fundamental reproductive biology. One difference is that fertilization occurs internally within women, not within men. A second difference is that women require a heavy 9-month investment of pregnancy

to produce a single child; men can produce that same child with as little as one act of sexual intercourse. And there are other key differences – women's fertility is cyclical, whereas men's fertility is not; women's fertility is sharply age-graded, whereas men's fertility is only gradually age-graded; post-partum, women incur the costs of breast-feeding, whereas men do not. SST posits that humans have evolved psychological and strategic mating adaptations to these sex-linked differences in reproductive biology.

Regarding the temporal dimension, humans have evolved a long-term mating strategy marked by heavy commitment, long-term pair-bonding, and biparental investment. This may seem obvious, but this sort of long-term committed mating is extremely rare among mammals, characterizing only 3–5%. Humans also have short-term uncommitted matings – one-night stands, casual hookups, brief affairs (e.g., Scelza 2011; Symons 1979). SST posits that the adaptive problems men and women recurrently had to solve differed as a function of this important temporal dimension.

Biological sex and temporal context generate a two-by-two matrix of adaptive problems, as shown in Table 1.

The Psychology of Short-Term Mating for Men and Women

Based in part on Trivers's (1972) theory of parental investment and sexual selection, SST posits that men had to solve adaptive problems of short-term mating such as increasing the number of sex partners accessible, identifying which women are sexually available or accessible, and minimizing the cost, risk, and amount of investment in each mating opportunity. A large volume of empirical data supports these predictions. Men, compared to women, are more motivated by short-term sex, desire a larger number of sex partners, let less time elapse before seeking sexual intercourse, find attractive women who display cues to easy sexual accessibility, and show a

Sexual Strategies Theory, Table 1 Mate selection problems men and women confront in short-term and long-term mating contexts

Mating type	Men	Women
Short-term	Increasing partner number	Immediate resources
	Identifying sexually accessible women	Evaluating ST as LT mates
	Minimizing cost and risk	Identifying good genes
	Minimizing commitment	Mate insurance, backup mates
	Identifying fertile women	Mate switching
Long-term	Paternity probability	Men able to invest
	Female reproductive value	Men willing to invest
	Commitment	Commitment
	Good parenting abilities	Good parenting abilities
	Gene quality	Gene quality
	Relationship load	Relationship load
	Longevity probability	Physical protection

Table is adapted from Table 1 of Buss and Schmitt (1993), p. 207

psychology and attendant behavior to minimize investment and entangling commitments in short-term mating contexts (Buss and Schmitt 1993; Haselton and Buss 2001; Schmitt 2003).

Women pursuing a short-term mating strategy face a different set of adaptive challenges. These include securing immediate access to economic resources, choosing sex partners with high-quality genes, evaluating short-term mates as potential long-term prospects, and cultivating potential backup mates for the goal of mate switching. Numerous studies support these predictions. Women prioritize extravagant resource displays in short-term mating (Buss and Schmitt 1993). They shift to preferring men high in masculine appearance and symmetrical features, two of which are hypothesized cues to good genes

(Gildersleeve et al. 2014). They cultivate backup mates, become distressed when their backup mates fall in love with others, and sometimes use short-term mating to exit an unhappy mating relationship to trade up to a better partner (e.g., Buss et al. 2017). SST, in brief, posits that both women and men have short-term mating within their strategic repertoire and that their psychology of short-term mating is differentiated in precisely the domains in which the sexes have had to solve different adaptive challenges of short-term mating recurrently over evolutionary history.

The Psychology of Long-Term Mating for Men and Women

In long-term mating, women and men face many similar adaptive problems, such as identifying a mate who will commit to them over the long haul, someone who will be a reliable partner, and someone who will be a good parent. Both sexes appear to have adaptations to solve these problems, such as looking for signs of love (a cue to commitment), prioritizing dependability and emotional stability in long-term mate preferences, and valuing good parent and good partner qualities such as kindness and agreeableness (Buss 1989, 2016; Buss and Shackelford 2008).

Men seeking a long-term mate have had to solve a critical adaptive problem – choosing a fertile mate or one who has high future reproductive potential. Since ovulation is relatively concealed in humans and fertility cannot be detected directly, SST posited that men would prioritize cues statistically correlated with fertility. Since women’s fertility is sharply age-graded, this yielded the predictions that men would prioritize physical attractiveness, since appearance provides a bounty of observable cue to youth and health and hence to fertility. Abundant empirical evidence supports this set of predictions. Men worldwide, compared with women, place a greater priority on physical attractiveness and relative youth in long-term mating (Buss 1989; Buss and Schmitt 1993; Kenrick and Keefe 1992). Due to

the adaptive problem of internal female fertilization and gestation, men seeking long-term mates also had to prioritize cues to mates that would increase probability of their paternity in offspring. And indeed, men place tremendous value on sexual fidelity in a long-term mate and dislike any indications of a history of promiscuous mating (Buss and Schmitt 1993). Men also have post-mate selection adaptations, such as sexual jealousy and mate-guarding effort, that function to increase the odds that their long-term commitment in one woman will result in offspring that are their own rather than those of rivals (Buss 2000; Daly et al. 1982).

SST posits that women pursuing a long-term mating strategy will prioritize, among other things, men who are both able to acquire resources and willing to invest those resources in them rather than in rival women. A large body of cross-cultural evidence supports this hypothesis. Women worldwide, compared to men, value resources and the qualities that lead to resources in long-term mates such as social status, ambition, and industriousness (Buss 1989). SST also posits that women had to solve the problem of protection and so will value men capable of protecting them from other men. Women indeed prioritize physical formidability, tallness, and athletic prowess, suggesting adaptations to solve this adaptive problem (Buss 2016).

Mating Psychology Is Context Dependent

Sexual strategies theory was designed as a complex theory of mating, positing a psychology contingent on biological sex and temporal context as central. Although abundant evidence has cumulated since it was first proposed in 1993, SST was designed to be open ended rather than the “last word” on evolved human mating strategies. Indeed, its authors articulated an agenda for future theorists and researchers that identified other likely contexts to which our psychology of mating would be contingent. One is *mate value* or a person’s level of desirability on the mating market. A second is *sex ratio* or the relative proportion

of men to women in any given mating pool. A third is an ecology of *parasite prevalence*. Research has confirmed that these and other contexts do importantly influence mating strategies (e.g., Buss and Shackelford 2008; Gangestad and Buss 1993; Schmitt 2016).

The authors of SST also speculated that individual differences were important and had to be explained by any complete theory of human mating strategies. Research since 1993 has increasingly focused on individual differences. As one example, research on the “dark triad” of personality traits (narcissism, Machiavellianism, and psychopathy) has shown that high scorers are more likely to pursue short-term mating, more likely to use deception as a mating tactic, and may even be more likely to use coercion or force by bypassing a cardinal feature of women’s mating strategy – female choice (Jonason et al. 2009). A second example, only dimly recognized by SST in 1993, is the importance of “good genes” in mate selection (e.g., Miller 2000).

Conclusions

Our evolved psychology of mating is extremely complex. We now know that theories of mating prior to SST were extraordinarily simplistic. Humans do not have a single mating motive that remains invariant across domains, temporal contexts, and biological sexes. Instead, humans have mating adaptations sensitive to temporal context, to the challenges each sex has recurrently faced, and to personal, social, and ecological factors such as mate value, sex ratio, and parasite prevalence. Every month, new “design features” of mating adaptations are being discovered, such as the importance of cues to sexual exploitability to short-term sexual attraction (Goetz et al. 2012), the relevance of personality to mating strategy pursued (Jonason et al. 2009; Schmitt 2016), and shifts from one sexual strategy to another depending on circumstances such as age, relationship history, ecology, and culture. Although we believe that SST, as originally formulated, provides many of the fundamentals of human mating that have been robustly supported by subsequent decades of

empirical research, much new knowledge has been discovered about mating that requires additions and expansions of its original formulation.

Sexually Antagonistic Hypothesis

Definition

Sexual antagonism happens when selective pressures influencing males and females differ and the genes experiencing these conflicting evolutionary forces are said to be sexually antagonistic (Innocenti and Morrow 2010).

Hence sexually antagonistic genes produce a “sexually antagonistic” phenotype, which is selectively favored in one sex but disfavored in the other sex (Rice 1984).

The Sexually Antagonistic Hypothesis tests possible models of genetic transmission of a trait (phenotype) and compares with other selective hypotheses and models such as direct selection, mutation-selection, stabilizing selection, frequency-dependent selection, genomic imprinting, maternal effects, and overdominance in order to understand how genetic variability is produced and maintained.

Introduction

Sexually antagonistic selection has been hypothesized and then empirically tested to understand why genetic variation is maintained at a much higher level than mutation-selection models would predict (Foerster et al. 2007) and has been studied as a counteracting force against extreme sexual selection (Rice 1984; Pischedda and Chippindale 2006; Chippindale et al. 2001).

Evolutionary theory predicts, in the absence of other counteracting forces, the progressive depletion of genetic variation in natural populations as a result of the effects of selection. However, empirical observations suggest that genetic variation is preserved for many traits, even if they are supposed to be under directional or stabilizing selection. Researchers commonly explain this paradox with mechanisms that may lead to a balance between mutation and selection. On the contrary, theoretical models testing the genetic variance equilibrium under mutation-selection balance predict a substantially lower genetic variance than the empirically observed one. This suggests a role for sexual antagonistic

selection (Foerster et al. 2007). If the optimal fitness diverges between sexes, as in the Sexual Antagonistic Hypothesis, then a high-fitness male transmitting its genes to daughters could produce low-fitness individuals, and conversely high-fitness females could do the same with sons. In a detailed analysis with *Drosophila* strains, Pischedda and Chippindale (2006) indeed found that in the case of sexually antagonistic traits, any potential genetic benefits of sexual selection are significantly reduced, and in some cases even reversed over one generation, again because high-fitness males produce low-fitness daughters and high-fitness mothers produce low-fitness sons.

Sexual Antagonistic Selection in Animals

Evolution based on the benefits of acquiring “good genes” in sexual selection is only plausible with the reliable transmission of genetic quality from one generation to the next. Accumulating evidence suggests that sexually antagonistic genes with opposite effects on fitness when expressed in the two different sexes may be common in animals and even plants. These sexually antagonistic genes should then weaken the potential indirect genetic benefits of sexual selection by reducing the fitness of opposite-sex progeny from high-fitness parents. The fitness reduction of opposite-sex offspring of high-fitness individuals has been shown in not only in *Drosophila* but also in birds and mammals.

This is particularly apparent in the Lek paradox. In birds such as the sage grouse which seasonally reproduce in leks, males gather to engage in competitive displays, and females chose the best males after carefully inspecting the display. In the lek there is strong female mate choice, and apparently nothing else than sperm is contributed by the male. Under these conditions, a persistent female choice for particular male trait should erode genetic diversity in male traits and thereby remove the benefits of choice. Logically female choice should lead to directional runaway selection, resulting in a

greater prevalence for the selected traits. This, however, does not happen in lek-breeding animals. One possible solution is the handicap principle. The handicap principle describes how costly male ornaments provide females with information about the male's inheritable fitness (Zahavi 1975). Another possible explanation is the presence of sexually antagonistic selection that continues to maintain genetic variation among males from one generation to the other, despite strong female choice.

Intralocus sexual conflict is in this case the sexual antagonism between alleles at the same locus, one at the advantage of one sex and the second at the advantage of the other sex. This kind of conflict represents a tug of war between natural selection on both sexes and sexual selection on one sex. For example, the bill color in zebra finches. This ornamentation could be costly to produce; it is important only for males in mate choice but also makes an individual vulnerable to predators. The alleles for such phenotypic traits are under antagonistic selection, and this conflict is resolved via elaborate sexual dimorphism thus maintaining sexually antagonistic alleles in the population. Evidence indicates that sexual antagonistic selection may be an important constraint in the evolution of many traits (Arnqvist, and Rowe 2005).

In mammals an emblematic example of sexually antagonistic selection in a natural population has been studied in the red deer (*Cervus elaphus*). The researchers, based on a very long-term individual observation across generations, suggested that male red deer with relatively high fitness fathered, on average, daughters with relatively low fitness. This was due to a negative genetic correlation between estimates of fitness in males and females and selection favors males that carry low breeding values for female fitness (Foerster et al. 2007).

Mountain sheep (*Ovis canadensis*) might present similar sexually antagonistic traits; the horns serve for defense from predators but also for head to head contest in male intrasexual competition, while horns in females serve only for predator

defense; hence the optimal fitness trait (shape of the horns) differs sharply from the optimal fitness trait in females (Rice 1984).

X chromosomes have been considered as hot spots for accumulating sexually antagonistic alleles, as W chromosomes in birds and butterfly; other autosomal locations have also been reported to harbor sexually antagonistic alleles (Pischedda and Chippindale 2006). Recently it has been estimated that around 8 % of the *Drosophila* genome could be sexually antagonistic and not only in the X chromosome but also chromosome n 2,3 and elsewhere in the genome (Innocenti and Morrow 2010). All these sexually antagonistic genes might result in strong, and previously unsuspected, counterbalancing effects on sexual selection and maintain trait variability despite selective forces.

The Sexually Antagonistic Hypothesis in Humans

In humans the Sexually Antagonistic Hypothesis has contributed to explorations of the Darwinian homosexual paradox. Recently, some researchers found that the evolutionary origin and maintenance of male homosexuality in human populations could be explained by the sexually antagonistic model, in which genetic factors spread in the population by giving a reproductive advantage to one sex while disadvantaging the other. In this case, contrary to what has been commonly found in animals, the advantage is to the female and the disadvantage to the male.

Homosexuality has for long time been considered a Darwinian paradox. Genetic evidence suggests that in part homosexuality is influenced by genetic factors. This does not, however, explain the persistence in the population of a (direct) fitness-reducing trait (homosexuality). As it was previously discussed in animals, fitness-reducing genetic factors should progressively disappear from the population, supplanted by the most fit trait, but this has not happened in the case of human homosexuality.

Empirical Data

Previous empirical work showed a genetic influence (Getz 1993; MacIntyre and Estep 1993). Further studies suggested that at least in male homosexuals there are more male relatives which are homosexuals in the maternal line. In parallel the female relatives on the maternal side of homosexual men show a significantly higher fecundity as compared to relatives of heterosexual men (Camperio Ciani et al. 2004; Jannini et al. 2010; Iemmola and Camperio Ciani 2009; Camperio Ciani et al. 2009).

Up to recently, most genetic models have failed to explain the maintenance of homosexuality in all population and at all times at a low frequency (2–10 %) but much higher than expected by a mutation selection model; hence the paradox was used to suggest homosexuality as a learned behavior (Nicolosi 1997).

Models Tested

Researchers have considered a range of different hypotheses for the genetic diffusion of male homosexuality. These included: direct selection modes in which the fitness is solely influenced by an individual's genotype; models based on overdominance (the genetic maternal effects on sons; models for the heterozygote advantage (as is found in malaria resistance) (King et al. 2005); and other selection models for male homosexuality which included maternal effects and genomic imprinting; possibly involving epigenetic activity; and finally a Sexually Antagonistic Hypothesis based model.

Gavrilets and Rice (2006) first showed that single locus genetic models could produce a stable low-frequency homosexuality distribution. Challenged by these competing hypotheses, Camperio Ciani et al. (2008) have studied a number of models for a single di-allelic locus at either an autosomal or X-linked location, and various selection modes in each case, under the assumption of random mating. Their analysis first identified the

range of selection parameters guaranteeing a stable polymorphism and the persistence of the trait in the population. These results confirmed Gavrilets and Rice's (2006) findings that single-locus models are largely unstable as their parameter ranges are too narrow to allow for stable polymorphism under the normal variability of population conditions. This leads to either fixation or extinction of the genetic factors, contrary to all empirical findings.

However, once all single locus models were excluded, Camperio Ciani et al. (2008) screened a large set of di-allelic models and excluded them one by one. It was concluded that only a sexually antagonistic model could explain all the empirical findings including stable low frequency homosexuality, higher fecundity only in females of the maternal side, and higher frequency of homosexuality in the maternal line. The winning model of sexually antagonistic selection involving at least two genetic factors – at least one of which must be on the X chromosome (inherited in males only through their mother) and the other on the autosomes – accounted for all the known empirical data such as stable persistence of homosexuality at relatively low frequency, higher frequency of homosexuals on the maternal side, and higher fecundity on all maternal side female relative to the homosexual probands.

All other models did not fit the empirical data, either implying that the alleles would become extinct too easily, or otherwise invade the population, or failing to describe the distribution patterns of male homosexuality and female fecundity observed in the families of homosexuals.

The sexually antagonistic model further suggested a higher fecundity of paternal aunts of heterosexual samples as compared to homosexuals which was overlooked in the empirical observation and subsequently confirmed (Camperio Ciani and Pellizzari 2012).

The strongest confirmation of the sexually antagonistic model, however, came recently by Sanders et al. (2015). These authors conducted a genome-wide linkage scan on 409 independent pairs of homosexual brothers (908 analyzed

individuals in 384 families) searching for genes influencing the development of male homosexual orientation. These researchers found the presence of gene(s) on the X chromosome in the q28 region (as suggested long ago by Hamer et al. (1993)) and presence of gene(s) in the pericentromeric region on the autosome n°8. These findings are strong empirical confirmation of the previous sexually antagonistic theoretical model and mathematical findings (Camperio Ciani et al. 2008).

The sexually antagonistic model best fit the interaction of male homosexuality with increased female fecundity within human populations, in a rather complex dynamic, resulting in the maintenance of male homosexuality at stable and relatively low frequencies, and highlighting the effects of heredity of homosexuality in males and fecundity in females, through the maternal line.

The sexually antagonistic model suggests new insights into male homosexuality in humans. In particular, these findings point, with a particularly relevant example, to the occurrence of firstly well-identified sexually antagonistic characters in humans. This perspective may help shift the focus away from male homosexuality per se: Rather than concentrating on the sole aspect of the reduced male fitness that it entails, this places male homosexuality within the more general sexual-conflict framework of a genetic trait with gender-specific benefits, which may have evolved by increasing the fecundity of females and which neither disappears nor completely invades the gene pool. Increasing fecundity in females might be the evolutionary origin of this genetic trait in human beings (Camperio Ciani, et al. 2012).

An unexpected implication of the new models concerns the impact that the sexually antagonistic genetic factors for male homosexuality have on the overall fecundity of a population. The findings suggest that the proportion of male homosexuals may signal a corresponding proportion of females with higher fecundity.

In other words, the Sexually Antagonistic Hypothesis for male homosexuality as a corollary

to the empirical findings suggest, contrary to common prejudice, that due to male homosexual influencing genetic factors when a population reduces fecundity (due to cultural or gene culture coevolution) the relative frequency of male homosexuals increase while the female fecundity in the maternal line of male homosexual relatively increases, thus buffering fecundity decline.

The possible widespread occurrence of sexually antagonistic characteristics in selective processes, which play their evolutionary game by giving a fecundity benefit to one sex while disadvantaging the other, has only recently begun to be appreciated both in animals and in humans (Camperio Ciani et al. 2015). Sexually antagonistic selection might be soon confirmed as a key mechanism through which high levels of genetic variation are maintained in biological populations.

Other candidate traits subject to sexual antagonistic selection in humans could be male nipples. Nipples in males may serve no selective function (Kunz and Hosken 2009) but carry the cost of a differentiated tissue subject to tumors and possibly degeneration (Korde et al. 2010). This trait is, however, maintained in males at a relative cost due to the large fitness benefit that nipples have in females for nurturing and infant survival. This might be the trait among others explained by the Sexually Antagonistic Hypothesis which benefits the female fitness at a relative cost of the male one.

Conclusion

In conclusion, sexually antagonistic traits and sexually antagonistic selection could be much more common than previously expected both in animals and humans. Male homosexuality is just the first example of an unknown number of sexually antagonistic traits, which contribute to the maintenance of the natural genetic variability of humans. The new perspectives opened by the models developed for sexually antagonistic selection may also contribute to a better

understanding of most genetically based sexual conflicts, which are, at present, poorly understood in humans.

Sexy Son Hypothesis

Simone Santoro

Department of Integrated Sciences, Faculty of Experimental Sciences, University of Huelva, Avenida de las Fuerzas Armadas, Huelva, Spain

Synonyms

[Sexy Sons Hypothesis](#); [Fisher process](#); [Fisherian process](#); [Fisherian runaway process](#)

Definition

The *sexy son hypothesis* provides a theoretical framework to explain the evolution of social polygyny by female choice (Weatherhead and Robertson 1979). In some circumstances, a female would benefit in long-term fitness (number of grand-offspring) by forming a pair with an already-mated male instead that with an unmated competitor. The advantage, the SSH claims, arises because their sons inherit the father's propensity to be polygynous and, therefore, prolific. The hypothesis was conceived for bird species where some females, as a consequence of mate sharing, achieve less reproductive success if they form a pair with a

polygynous male instead that with a monogamous one. Over time, the hypothesis has been applied to other species, such as humans, and its conceptual framework extended to different aspects of mating system theory.

Introduction

According to Fisher (Fisher 1915), male ornaments result from the intersexual selection, that is, the female choice of males with exaggerated sexual secondary characteristics (ornaments). This hypothesis, known among others as the *Fisher process* or *runaway Fisherian process* (or selection), fell into oblivion for many decades and was rediscovered only in the 1980s (reviewed by Andersson 1994). The *sexy son hypothesis* (SSH) dates back a few years, which is probably the reason why the authors (Weatherhead and Robertson 1979) did not mention Fisher's work. Though, notable similarities exist between the two theoretical frameworks to the point that the two hypotheses are often confused with each other and, in the evolutionary literature, the term *sexy son* (or *sexy sons*) is usually a synonym of the *Fisher process*. The SSH was framed within a different context, that of the Polygyny Threshold Model (PTM, Orians 1969), which attempts to explain the evolution of social polygyny through female choice. According to the PTM. The breeding situation provided by a polygynous male to the female, according to the PTM, might be so much better than that of a monogamous male, that this difference would compensate for the loss of male assistance. The PTM yielded little empirical support as, on average, the females paired with monogamous males tend to raise more offspring than those mated to polygynous males (but see Santoro 2019 for a critical review of the hypothesis-testing framework of both PTM and SSH). Thus, the SSH expanded the PTM framework from the direct (offspring) to the indirect (grand-offspring) benefits the females mated to polygynous males would obtain through *sexy sons*. Overall, the foundation of both the PTM and SSH lays on the concept of *polygyny threshold*, that is, the point at which the difference

between the breeding situation (PTM) or genetic (SSH) quality of a monogamous and a polygynous male is great enough that a female would have similar fitness by forming a pair with one or another.

Controversies and Obstacles for the Hypothesis Testing

The SSH has been thought-provoking and controversial, raising many doubts in the theoretical and empirical field, especially regarding the hypothesis-testing framework (Huk and Winkel 2008; Santoro 2019). The first controversy raised by the SSH was about the possibility that males mislead females about their mating status. If the female cannot discern the mating status of the available-to-mate males, then the SSH's starting argument no longer holds. The chance this happens should depend on the reproductive biology of a species or even of a given population. Experimental evidence shows that females can discriminate the mating status of males, even in small passerine birds. Another controversy was on whether females might recoup initial (i.e., offspring) reproductive losses through *sexy sons*. This issue, raised by Kirkpatrick (1985), reveals the underlying similarity and difference between the SSH and the *Fisher process*. Both of them entail costs, but for different sexes. In the *Fisher process* the cost is for the chosen sex whose trait (e.g., ornament) evolves by the trade-off between sexual and natural selection, which respectively favors and limits it (the latter when the trait becomes detrimental to its survival). In the SSH, however, the cost is for the choosy sex. Kirkpatrick's models suggested that such an evolutionary process was impossible, something that, however, posterior analyses confuted (Pomiankowski et al. 1991). Other two controversies were on the unclear predictions of the SSH about the difference in fitness of the first (or primary) and the second (or secondary) female, and on the focus being on the population-level average outcomes instead that on the individuals' fates (Santoro et al. 2019).

The Sexy Son Hypothesis in Humans

Albeit the SSH was ideated for socially polygamous mating systems, where a female forms a breeding association with a male; it has been expanded especially in humans to the case of genetic polygamy by promiscuity. Thus, in *Evolutionary Psychology* (Wright 1994), the *sexy son* strategy consists of some females “mating promiscuously with sexually attractive males (handsome, brainy, brawny, and so on), risking the high male parental investment they might extract [by a monogamous relationship] but gaining the likelihood that any sons will be, like their fathers, attractive and therefore prolific.” The *sexy son hypothesis* in humans, therefore, seems to be used more frequently in a sense more akin to the *Fisher process* than to the original idea of SSH to explain the evolution of social polygyny.

Conclusion

The scope of the SSH is to provide a theoretical framework capable of explaining the evolution of social polygyny by female choice. Although often equated in literature, the *sexy son hypothesis* and the *Fisher process* are not equivalent so that it would be appropriate to differentiate the intellectual authorship of the two conceptual brands. Finally, it is worth mentioning that the female choice alone may not be sufficient to justify the mating systems evolution. As some think (e.g., Davies 1989), at least to some extent, sexual conflicts are likely to exist with one sex gaining benefits to the expense of the other.

Method of successive approximations

Definition

The development of a new operant behavior using reinforcement of successive approximations of that behavior.

Introduction

Shaping is a procedure developed by Skinner, involving the presentation of reinforcement for exhibiting successive approximations of a target behavior. Successively closer approximations of a behavior are reinforced until the individual exhibits the desired response (terminal behavior).

Skinner's First Experiments and the Invention of the Term "Shaping"

Skinner first described the method of response differentiation by mechanically reinforcing successive approximations in 1938 (Skinner 1938) but had not used the term shaping until several years later in 1951. He conducted the first experiment using free-form shaping by hand (as opposed to via a mechanical device) a few years later in 1943, while working on Project Pigeon in Minnesota (Peterson 2004). Skinner

later said, referring to this occasion that "possibly our most impressive experiment concerned the shaping of behavior" and also noted "how much easier it was to shape behavior by hand than by changing a mechanical device" (Skinner 1979, p. 268). This event helped Skinner appreciate the significance of the reinforcement being mediated by biological connections with the animate social environment, as opposed to solely mechanical (Peterson 2004). The term *shaping* was first formally introduced in 1951: "The reinforcement gives you a means of control over the behavior of the animal. It rests on the simple principle that whenever something reinforces a particular activity of an organism, it increases the chances that the organism will repeat that behavior. This makes it possible to shape an animal's behavior almost as a sculptor shapes a lump of clay" (Skinner 1951, pp. 26–27).

The Shaping Procedure

Shaping (Skinner 1951) is a process where successive approximations of a behavior are reinforced, resulting in a gradual generation of the desired response (Powell et al. 2017).

According to Martin and Pear (2015), the following dimensions of behavior can be modified via a shaping procedure:

- Topography (form): Physical movements involved in the behavior
- Frequency: Number of instances of the behavior in a time period
- Duration: Continuous amount of time that the behavior lasts
- Latency: Time between the controlling stimulus and the behavior
- Intensity (force): Amount of energy expended on the behavior

An effective use of shaping involves (1) defining a well-specified terminal behavior, (2) choosing a starting behavior that is within the individual's repertoire, (3) preselecting the steps that qualify as successive approximations, and (4) moving through the shaping steps at an

appropriate pace – neither too fast nor too slow but be remaining flexible as progress is monitored (Martin and Pear 2015).

Behavior Modification Using Shaping

Shaping can be used to facilitate the demonstration of a particular response when an organism either lacks the skill or is not inclined to perform a desired behavior. Shaping can successfully be used in the process of learning a complex behavior or skill and has therefore useful applications in education (Snowman and McCown 2012). By reinforcing gradually increasing in complexity behaviors that resemble the desired outcome and ignoring those that do not, a person gradually develops the necessary skills and moves closer to completing a complex task.

Miltenberger (2016) advises to use the steps below to ensure that shaping is used appropriately:

- (i) Define the target behavior
- (ii) Determine whether shaping is the most appropriate procedure (shaping is appropriate for acquiring new behaviors)
- (iii) Identify the starting behavior (the first approximation, which must have some relevance to target behavior)
- (iv) Choose the shaping steps (each step must come closer to target behavior, but must require neither a too close or a too far change in behavior)
- (v) Select the reinforcers to be used in the procedure (ensure that the consequence is reinforcing for the individual, and reinforce immediately)
- (vi) Differentially reinforce each successive approximation of the target behavior when it occurs (when the behavior occurs reliably, start reinforcing next approximation while ceasing to reinforce the previous one)
- (vii) Move through the steps at a proper pace (move to the next approximation after a few successful exhibitions of behavior, and facilitate behavior by communicating

expectations and prompting appropriate behaviors)

Miltenberger (2016) describes a number of studies showing that shaping has various successful applications. Target behaviors such as verbal communication, toilet training, athletic performance, compliance with medical interventions, etc., can be facilitated through shaping in a variety of settings (classroom, home, therapeutic centers). It can also be used across various populations including children (Smeets et al. 1985), adults (Howie and Woods 1982), individuals with intellectual disabilities (Hagopian and Thompson 1999), and children with autism (Newman et al. 2009).

Conclusion

Shaping, the reinforcement of successive approximations of a behavior, can be used to facilitate the demonstration of a behavior when an individual may lack the skill or may lack motivation to perform it. Through shaping, several dimensions of a behavior can be modified, such as form, frequency, duration, latency, and intensity. The shaping procedure has several successful applications with a variety of populations and settings.

Shifting Dominance

Sarah J. Wofford¹ and Paul A. Moore²

¹Laboratory for Sensory Ecology, Bowling Green State University, Bowling Green, OH, USA

²Laboratory for Sensory Ecology, Department of Biological Sciences, Bowling Green State University, Bowling Green, OH, USA

Definition

Dominance alludes to a superior social status over other conspecifics that allows an individual exclusive or preferential access to resources. Shifting dominance denotes the alteration of social status such that a dominant individual becomes subordinate or vice versa. Transitional Power, Temporary Hierarchies, RHP.

Introduction

The establishment of dominance relationships dictates an organism's ability to access resources necessary for survival and reproduction. These dominance relationships are established based on intrinsic (i.e., body size, weaponry, aggressiveness) or extrinsic (i.e., prior experience, resource ownership) variables and result in a dominant and subordinate individual. Often, the status of "dominant" and "subordinate" is reference against individuals and are not necessarily global attributes of an animal. In animal populations, dyadic dominance relationships have the potential to manifest as multiindividual dominance hierarchies in which some individuals are consistently dominant to others. The establishment and maintenance of these hierarchies are beneficial in that they can allow organisms to reduce the time and energy allocated to contests (recognizing and submitting to a dominant individual reduces the chance of injury). However, hierarchical status can also be costly if organisms are unable to break away from a subordinate rank (subject to lower amounts or reduced quality of resources) or if a dominant

animal must constantly patrol and engage in intimidation tactics to maintain a dominant rank (Sapolsky 2005).

Hierarchy Formation

Crayfish (decapod crustaceans) are well known for their agonistic behaviors and the subsequent hierarchies that result from these contests. Due to high population densities, crayfish are in constant competition over access to resources and ideal microhabitat conditions. One of the most highly embattled resources is access to shelters as crayfish are preyed upon by several terrestrial and aquatic species, including conspecifics (Moore 2007). Establishment of dominance relationships and subsequent hierarchies can reduce the time and energy used to engage in contests and can guarantee resource access. Consequently, crayfish are known to rapidly establish stable, linear hierarchies (within 6 to 12 hours) that are considered relatively long lasting (up to 1 week) (Goessmann et al. 2000). However, the establishment of these hierarchies is chaotic, with several agonistic interactions and dominance shifts occurring. Furthermore, the duration of the stability of these relationships has been called into question. Firstly, the bulk of hierarchical stability studies that have been carried out are commonly performed in populations of no more than ten individuals confined to a finite space. This sets up a limited contestant pool with inhibited chances for escape which is not ecologically realistic. Moreover, there are several factors that play a role in agonistic interactions and subsequent establishment of dominance relationships which, when altered, can introduce very different hierarchical dynamics (Breithaupt 2011; Moore 2007).

Studies of agonistic interactions in crayfish have revealed that dominance relationships can shift due to alterations in contest experience (i.e., winner/loser effects), hormonal concentrations (e.g., serotonin), or information availability (Huber et al. 2001; Moore 2007). While each of these factors has been studied, and will be

presented here, as separate variables, it is important to note that each of these variables is intricately linked to affect dominance relationships and hierarchy establishment.

Several studies have shown that olfactory or chemical information plays a significant role in the dynamics and outcome of dyadic contests and hierarchy establishment. Specifically, crayfish urine has been implicated as a major source of chemical information during agonistic interactions. Although the primary function of this urine release is osmoregulatory, (Vogt 2002) individuals release urine significantly more often during agonistic contests than in nonagonistic behaviors. Furthermore, the timing, frequency, and amount of urine released are linked to the status of an individual and the eventual outcome of the contest (Breithaupt 2011). It is currently unclear whether urine release is meant as a signal of dominance or subordination. However, recent work has suggested that the chemical message might be context dependent. Regardless, absence or alteration of this chemical information can delay or inhibit the establishment of dominance relationships. Alternatively, exposure to chemical signals, even without social contact, has the ability to influence one's subsequent hierarchy rank (Breithaupt 2011).

Changes to an organism's social experience (i.e., winning or losing a contest) can also significantly affect subsequent interactions and establishment of dominance relationships. Crayfish have shown evidence of both winner and loser effects, as both winning and losing experiences have influenced the outcome of successive interactions (Moore 2007). For example, individuals that were given winning experiences, by being paired with smaller animals, were more likely to win future contests even when paired against hypothetically superior opponents (i.e., larger or resource-holding opponents) (Daws et al. 2002). However, winner and loser effects are finite. Winner effects have been shown to last anywhere from 40 minutes to 24 hours in crayfish (Moore 2007; Seebacher and Wilson 2007). Loser effects have been demonstrated, but duration of the effect is currently unknown. Furthermore, the frequency

with which individuals interact with each other can influence the stability of these dominance relationships. Larger populations (>30 individuals) of crayfish have been shown to exhibit varying fight dynamics (i.e., fewer, shorter contests) and reduced longevity of social recognition, causing the dominance relationships to be much more loosely associated (Patullo et al. 2009).

Changes in status through altered social experiences are accompanied by modification of hormonal composition and concentration which, in turn, influences behavior. For instance, social status (i.e., dominant or subordinate) affects the responsiveness of some neurons to circulating serotonin, in turn, altering the likelihood of an escape response (Yeh et al. 1996). Likewise, manipulative changes to circulating hormone concentrations can alter behavior. Exposure to certain neuromodulators (e.g., monoamines such as octopamine or serotonin) can influence performance in subsequent contests in crayfish. Serotonin has been shown to modulate aggression, agonistic displays (e.g., meral spread), and contest escape response (i.e., tail-flips) in such a way that serotonin injections prior to or during a contest can influence dominance rank outcome (Huber et al. 2001).

Conclusion

Establishment of dominance relationships is beneficial due to the reduction in time and the energy utilized to obtain vital resources when in competition with conspecifics. However, the stability and longevity of these relationships are dependent on several, interconnected factors. As social contexts and information availability change, so do contest dynamics and dominance relationships.

Shortcomings of the SSSM

Vincent Barnett
London, UK

Definition

The term "Standard Social Science Model" (SSSM) was first proposed by John Tooby and Leda Cosmides in their contribution to *The Adapted Mind* (Tooby and Cosmides 1992). The SSSM is based on the assumption that "the human psychological architecture consists predominantly of learning and reasoning mechanisms that are general-purpose, content-dependent, and equipotential . . . That is, the mind is blank-slate like, and lacks specialized circuits that were designed by natural selection to respond differentially to inputs" (Tooby and Cosmides 2005, p. 6). In the SSSM, the pre-existing or innate architecture of the mind is posited to have little or no role in determining behavior, which is instead conceived as being determined by social learning processes plus cultural traditions and environmental contexts.

Introduction

This entry will expand on the nature of the criticisms of the SSSM provided by evolutionary psychologists such as Tooby and Cosmides in part by contextualizing these criticisms alongside the various different extant methodologies of the SSSM. It will also discuss the relevance of evolutionary psychology more specifically to the methodology

of economics, outline the history of the development of the SSSM, consider some reasons why the SSSM has been so persistent, and also discuss some criticisms of Tooby and Cosmides' presentation of the SSSM that have been made in the literature.

In contrast to the SSSM, evolutionary psychologists assert that the mind is (in substantial part at least) composed of many evolved psychological mechanisms that are very specific in content and problem-focused in nature, and which play a very significant role in determining behavior. Two of the founders of evolutionary psychology have, in consequence, argued that "the social science project of the past century is not only wrong but radically misconceived" (Tooby and Cosmides 2005, p. 6). As they have explained:

The blank-slate assumption [of the SSSM] removes the central causal organizers of social phenomena - evolved psychological mechanisms - from the analysis of social events, rendering the social sciences powerless to understand the animating logic of the social world . . . For example, the nature of the social interactions between the sexes are partly rooted in the design features of evolved mechanisms for mate preference and acquisition. (Tooby and Cosmides 2005, pp. 6–7)

The SSSM is, therefore, methodologically stunted in this instance because it assumes that men and women make decisions about partner choice and reproduction using the same behavioral criteria, when, in fact, the cognitive architectures relating to these issues that have evolved in the two sexes are different in some very significant ways.

The Methodologies of the Social Sciences

Before claiming that something is "wrong and radically misconceived," as has been suggested by Tooby and Cosmides vis-à-vis the SSSM, the precise nature of the "something" needs to be carefully outlined. By inventing and promoting the phrase "Standard Social Science Model" (SSSM), Tooby and Cosmides might be taken to imply that all the social sciences utilize the same method or, at the very least, all the different social science methodologies share some common

methodological features. It will be suggested here that this latter proposition is much more accurate, as the social sciences evidently employ various different methodologies, but they do have some significant features in common. Therefore, it is necessary to explicitly outline the various different social science methodologies, in order to then identify their essential common features.

The three basic methods that have been identified as being employed in the mainstream social sciences are positivist, interpretive, and critical methodologies. Positivist methodology employs objective empirical observations combined with deductive logic in order to attempt to detect causal laws relating to human behavior; it is, therefore, quantitative and objective in nature. Interpretive methodology attempts to detect the meaning behind social actions and behaviors and how people create and maintain their social worlds; it is, therefore, constructivist and analytical in nature. Critical methodology attempts to uncover the real structures and processes that underlie the social world and also how they can be improved; it is, therefore, activist and quasi-political in nature (Garcia and Poston 2008, pp. 108–109). It can readily be seen that these three methodologies are in some senses quite different, but even so, they do share some important common elements.

From the perspective of evolutionary psychology, the three common most central (and erroneous) features of all three social science methodologies are as follows:

1. Social constructivism: that all human behavior is primarily determined by external social structures or exogenous cultural phenomena, such as class or gender
2. Individual homogeneity: that human beings are all behaviorally homogeneous, that is, they all calculate mentally in the same way when making behavioral computations
3. Cognitive void: that every human mind is born as a “blank slate,” with only a few inbuilt general processing mechanisms, on which cultural impressions, socialization, and “learning” are then applied (Barnett 2015, pp. 652–653)

In contrast to these three erroneous assumptions of the SSSM, evolutionary psychologists posit instead that a significant portion of (but certainly not all) human behavior is primarily or at least partly determined by inbuilt programming; that human beings are behaviorally heterogeneous, for example, that men behave (on average and in some ways) very differently from women; and that the human mind is born containing a significant amount of inbuilt cognitive architecture that has been evolved by processes of natural and sexual selection.

In addition, there are some other aspects of the SSSM that are questioned by evolutionary psychologists. For example, “the concept of ‘learning’ within the Standard Social Science Model itself tacitly invokes unbounded rationality, in that learning is the tendency of the general-purpose, equipotential mind to grow” (Tooby and Cosmides 2005, p. 13). Therefore, according to the SSSM:

... humans are endowed with a powerful, general cognitive capacity (intelligence, rationality, learning, instrumental reasoning), which explains human thought and the great majority of human behavior. In this case, humans putatively engage in successful social exchange through exactly the same cognitive faculties that allow them to do everything else. (Cosmides and Tooby 2005, p. 585)

This notion of learning equipotentiality is challenged by evolutionary psychologists, who maintain instead that natural and sexual selection processes would have favored the evolution of very specific cognitive architecture devoted to solving very particular problems. For example, specialized cognitive architecture devoted to social exchange calculations would have evolved, and this architecture would be computationally separate from other psychological mechanisms devoted to other specific tasks.

The Ten Steps of the SSSM

In addition to the basic case against the SSSM presented thus far, Tooby and Cosmides have also outlined a more detailed account of the intellectual

assumptions of the SSSM in 10 separate steps as follows:

- Step 1: Genetic variation does not explain why human groups differ dramatically from each other in thought and behavior. According to Tooby and Cosmides, this is the only step of the SSSM that is correct.
- Step 2: Although infants everywhere are the same, adults everywhere differ profoundly in their behavior and thought; therefore a fixed human nature cannot be the cause of these profound differences.
- Step 3: Because adult mental organization is absent from infants, they must acquire it from outside sources during their childhood development.
- Step 4: These outside sources are existing behavior in the social world and also culture.
- Step 5: The social and cultural elements that mold the individual both precede them and are external to them.
- Step 6: What determines the substance of human life – behavior, traditions, knowledge, social structures, and so on – is extragenetic culture.
- Step 7: The directional flow of influence is from the outer social world inward into the individual person.
- Step 8: Phenomena at the sociocultural level are mostly or entirely caused by other phenomena at the sociocultural level.
- Step 9: Therefore, something called human nature cannot play any notable role in generating social organization.
- Step 10: Psychology is, in consequence, merely the discipline that studies the processes of socialization through learning and through which individual psychological character is acquired (Tooby and Cosmides 1992, pp. 25–30).

Tooby and Cosmides argue that steps 2–10 are all based on faulty or naïve reasoning. For example, the fact that some aspects of adult mental content appears to be absent at birth is not relevant to deciding whether they are part of the inbuilt architecture of the mind or not, as female breasts are absent at birth, yet they still develop during

maturation. As they have explained: “In the worldview of the SSSM, biological construction goes on in the uterus, but at birth the child is ‘biologically complete’ except for growth; at this point, it is surrendered into the sole custody of social forces” (Tooby and Cosmides 1992, p. 81). This view is mistaken because it conflates the question of whether something is fully expressed at birth with whether a developmental mechanism for it is present at birth, which will be expressed at some point during maturation.

As another example, the idea present in the SSSM that “biological factors” are entirely separate from environmental factors is a naïve formulation of the relationship, as environmental influences require evolved cognitive architecture to act upon. As Steven Pinker has outlined:

The SSSM proposes a fundamental division between biology and culture. Biology endows humans with the five senses, a few drives like hunger and fear, and a general capacity to learn. But biological evolution, according to the SSSM, has been superseded by cultural evolution. Culture is an autonomous entity that carries out a desire to perpetuate itself by setting up expectations and assigning roles, which can vary arbitrarily from society to society. (Pinker 1999, pp. 44–45)

Instead of biology being “completely abdicated as an explanatory force in shaping human behavior” in the SSSM, evolutionary psychologists posit the accuracy of an interactive model in which both cultural and biological factors play important roles in determining this behavior (Saad 2011, p. 27). As Tooby and Cosmides have explained, “any learned behavior is the joint product of ‘innate’ equipment interacting with environmental inputs” (Tooby and Cosmides 2005, p. 31). They call this more realistic interactive model the integrated causal model (ICM), which posits the existence of a large number of content-specific psychological mechanisms that are adaptations to various problems that were faced in the evolutionary past (Tooby and Cosmides 1992, p. 49).

Another example of the difference between the SSSM and the ICM is that instead of the general and rather vague notion of “culture,” which forms a key part of the SSSM, Tooby and Cosmides posit that, in fact, culture is divided into two basic but separate components, evoked culture

and transmitted culture. Transmitted culture is what adherents of the SSSM usually mean by the term culture, i.e., ideas and behaviors that have been created in one mind and then transmitted to others. The concept of evoked culture is something unique to evolutionary psychology and the ICM, as it is pre-existing but dormant programming that is triggered in some groups more than others in relation to contingent encounters with specific environments. This distinction in the ICM is important in that it allows a more sophisticated account of cultural evolution than is possible in the SSSM, as evoked culture encompasses the differential activation of psychological mechanisms across space and time.

Finally, Tooby and Cosmides have explained that, when it appears that something could be an innate property of the mind, “the SSSM-oriented anthropologist or sociologist riffles through the ethnographical literature to find a report of a culture where the behavior (or whatever) varies . . . Upon finding an instance of reported variation,” the behavior is deemed to be socially constructed rather than innate (Tooby and Cosmides 1992, p. 43). The founding text of this “find behavioral variation” method of social attribution is declared to be Emile Durkheim’s late nineteenth-century book *The Rules of Sociological Method* (Durkheim 1962 [1895]). This method was subsequently adopted within anthropology by Franz Boas, whose student Margaret Mead was the author of the infamously misleading statement: “human nature is almost unbelievably malleable” (Salmon and Crawford 2008, p. 8).

However, the fact that, for example, many diverse languages are found across the globe is not in itself conclusive proof of the hypothesis that there is no species-general language acquisition instincts present in humans being at birth. It is quite possible that everyone is born with innate language-use programming, but how this programming is deployed in each individual is framed by the cultural traditions of the particular regions in which they are born and live, this combination of innate instincts plus cultural variations producing the many diverse languages across the globe.

A Short History of the SSSM

In order to understand how the SSSM has become so prevalent, its historical development requires some consideration. It can reasonably be suggested that the contemporary SSSM was created out of intellectual foundations developed across the nineteenth century and into the early twentieth century. However the idea of the human mind as a “blank slate” goes back to the philosopher John Locke, who used the phrase *tabula rasa* to describe the mind at birth in his *Essay Concerning Human Understanding* (1690).

By the mid-nineteenth century, social theorists such as Auguste Comte and Karl Marx had developed various social science concepts such as class, intuitively building on Locke’s assumption that experience rather than innate knowledge was the driving force of all social understanding. In the second half of the nineteenth century, a proto-Darwinian approach to psychology was developed in the works of Herbert Spencer and William James. Spencer and James both wrote the book entitled *The Principles of Psychology* in which evolutionary approaches to understanding the nature and function of instincts were promoted (Spencer 1855, p. 542; James 1891). Darwin explicitly acknowledged Spencer’s claim to priority in this innovation at the end of *The Origin of Species* (Darwin 1872 [1859], p. 428).

However, in the early twentieth century, the influence of behaviorism in psychology (and in the social sciences more generally) grew significantly, mainly through the work of J.B. Watson and B.F. Skinner. The behaviorist program “adopted the mechanist conditioning paradigm, focusing on the search for universal laws of learning,” for example, through experiments on the conditioning of small animals such as rats (Parker 1990, p. 23). As Watson explained, in a completed system of behaviorist psychology “given the response the stimuli can be predicted; given the stimuli the response can be predicted,” a simple mechanical view of animal behavior (Watson 1996 [1913], p. 262). Equipotentiality was also asserted: the same learning mechanisms were seen to apply to all stimulus/response reactions. Investigations into “mental states,”

consciousness, or constituent elements of the mind – i.e., consideration of instincts – were subsequently banished from psychology as being overly speculative and too imprecise for accurate measurement. By this means, investigations into the cognitive aspects of behavior were dropped from the psychologist's research program.

In parallel with this de-cognitization process in psychology, some of the other social sciences such as economics underwent similar de-psychologization trends. This is illustrated by the fact that some early twentieth-century economists had explicitly operated within a James-type instinct psychology framework (Barnett 2017a, b; Cosmides and Tooby 1994) and that at the end of the nineteenth century, it was declared by one well-known economist that “psychology must be to political economy - like the deity of Boethius – ‘path, motive, guide, origin, and end’” (Wicksteed 1899, p. 140). However, even though psychology had been an important component of many early economic theories, the formal separation of economics from psychology based on mathematical maximization concepts was eventually completed by economists in the 1930s/1940s (Bruni and Sugden 2007, p. F1). This meant that any pre-existing or residual focus on instincts in economics was dropped completely after World War II.

In turn, most of the social sciences subsequently adopted the social constructivist approach: focus was placed only on external structures and processes, e.g., class and gender in the case of sociology or kinship systems and linguistic structures in the case of anthropology (Evans 2005, p. 50). The concept of instinct still remained alive within the mid-twentieth-century ethology program, but this type of ethological approach had no influence at all on any of the social sciences after World War II.

Shortcomings in the Methodology of Economics

In parallel with the SSSM/ICM contrast, it can be argued that much contemporary mainstream

economics is also founded on “wrong and radically misconceived” principles, as it is based on the doctrines of methodological individualism and rational choice theory. These state that individual human beings are atom-like, separate units, the behavior of which is invariably grounded in individualistic motivations and which are focused exclusively on the maximization of certain specified units such as utility, consumer satisfaction, or pleasure, subject to various constraints (Basu 2008, p. 586; Rubin and Capra 2012, p. 7).

For example, one well-known and influential definition from the 1930s stated that economics studied human behavior as the relationship between ends and scarce means with alternative uses, clearly implying a type of resource-use optimization process. In direct contrast with this, the concept of inclusive fitness (or close family interest) proposed by evolutionary biologists as a foundation for their subject directly contradicts the individual maximization approach of mainstream economics. For evolutionary biologists, individuals attempt to maximize their inclusive fitness rather than their individual self-interest, which means that they aim to maximize their reproductive success rather than their individual utility, and any optimizing use of external resources is focused on fulfilling family interests, not individual self-interest.

In contrast to both economics and evolutionary biologists, evolutionary psychologists maintain that “observed human behavior dramatically and systematically departs from sociobiological predictions of generalized fitness striving (as well as the predictions of economic rationality ...)” (Tooby and Cosmides 2005, p. 13). Instead of single-factor maximization models, which posit, for example, that either individual fitness or inclusive fitness is maximized, evolutionary psychologists maintain that organisms act by following the evolved logic of the many psychological mechanisms that have been built into their neural architecture by natural and sexual selection processes that have operated over the evolutionary past. This means that animal behavior is much more complex than any single-factor maximization

model; instead, a range of different aims and goals are pursued at different times and in relation to different ecological contexts by the activation of various different psychological mechanisms, these goals sometimes being in conflict with each other.

This means in turn that the approaches of both methodological individualism and rational choice theory as currently deployed within mainstream economics are far too simplistic to be accurate. In addition, heterodox approaches to economics such as institutionalism and Marxism are also inaccurate in that even though they posit different foundations for the subject than the mainstream approach, these foundations are also too simplistic in their presentations of the many factors that go toward determining human behavior.

Why Has the SSSM Remained So Persistent?

It is worth considering some reasons for why the SSSM has persisted for so long in the social sciences across much of the twentieth century, despite recent research suggesting that it is flawed. One reason or part of the explanation is that Locke's tabula rasa conception of the mind as a "blank slate" goes back so far in the Western philosophical tradition that it has become ingrained in the social science collective consciousness and is accepted by some without question.

Another hypothesis for part of the explanation could be termed the political agenda hypothesis, and relates to the prevalence of what was previously characterized as critical methodology in some of the social sciences. The use of the critical method entails that some social scientists do not see themselves as neutral scientific observers, i.e., as devoted to presenting an objective view of how societies function, just as natural scientists do for the natural world. Instead, many "critical method" social scientists see themselves more as political activists devoted to changing the world for the

better, in terms that they define individually for themselves. In this case, they do not want to employ a methodology that is scientifically objective, but instead choose to adopt an instrumentalist methodology which supports their particular vision of social change.

However, when critical methodology is presented in this way it becomes apparent that it is not social science; it is political activism acting under the guise of science. This activist methodology is very reluctant to accept that there are any biological influences on behavior, as this is seen to potentially constrain or hinder the process of transforming the existing "wrong" world into the future "correct" world. Thus, the SSSM is still thriving, in part, because it is seen as providing a natural intellectual platform for critical method political activism.

Criticisms of Tooby and Cosmides' Account of the SSSM

Various criticisms of Tooby and Cosmides' articulation of the SSSM model have been presented, as in the book *Alas, Poor Darwin: Arguments Against Evolutionary Psychology* (2001), which (as the title suggests) is generally skeptical of the evolutionary psychology framework. In this book it is suggested that Tooby and Cosmides' argument against the SSSM illicitly switches between stating that in the SSSM the social is posited as not reducible and then suggesting that the cultural is posited as not reducible. As has been explained:

Where in the case of Durkheimian sociology the model is flawed because it postulates the social is not reducible to another level, Geertzian anthropology is flawed because it argues that the cultural is not reducible. Thus the central concept of the SSSM slips opportunistically between the "social" and the "cultural" according to the discipline under criticism. (Rose 2001)

However this criticism is easily dealt with in that Tooby and Cosmides actually suggest that, in their ICM, both the social and cultural realms are seen as being inextricably linked to the psychological

mechanisms that have evolved within the environment of evolutionary adaptedness (EEA). The fact that Tooby and Cosmides' criticism applies to both social and cultural realms is not therefore fatally problematic.

Other more substantive criticisms have been made of Tooby and Cosmides' use of the EEA concept. It has been argued that their view of the EEA is too simplistic and uniform, in that the EEA(s) might have been more diverse and heterogeneous than Tooby and Cosmides suggest. It could also be more difficult to accurately specify what adaptive problems were faced by our Pleistocene ancestors than Tooby and Cosmides allow; hence it might be more difficult to specify what psychological mechanisms have evolved (Mameli 2007, pp. 26–28). Elsewhere, it has been argued that the Tooby and Cosmides theory of mind – the brain conceived simply as an information-processing computer – is deficient in that it neglects environmental and bodily interactions (Barrett 2012, p. 24).

In response to such a range of criticisms, it is important to distinguish between those criticisms that reject the Tooby and Cosmides framework entirely, and those that accept many of the basic premises, but suggest that some of the specific ways in which Tooby and Cosmides apply evolutionary theorizing to understanding neural architecture might be flawed in some ways. The latter types of criticisms are generally more plausible than the former. As another example, it has been argued that, in order to become more realistic, evolutionary psychology needs to re-employ the nongenetic evolutionary processes that help individuals to adapt to their current environments that have been mistakenly rejected as part of the wider rejection of the SSSM by evolutionary psychologists such as Tooby and Cosmides (Wilson 2010, p. 122). Tooby and Cosmides might respond by pointing out that their concept of transmitted culture should be taken to include such nongenetic evolutionary processes within it.

Conclusion

Tooby and Cosmides' critique of the SSSM is a powerful and original – if highly controversial

outside of the bounds of evolutionary psychology – means of conceptualizing the development of the mainstream social sciences as they have developed over the past two centuries or so. If their criticisms of the SSSM are correct, as they have outlined, it would then mean that “the existing superstructure of the social and behavioral sciences . . . will have to be dismantled” (Tooby and Cosmides 2005, p. 6). Put more bluntly, the social sciences are all currently constructed on faulty foundations. In fact it could be suggested that, in addition to the social sciences being falsely constructed, the humanities are similarly erroneously grounded, as they currently utilize similar methodologies to the social sciences (Wilson 2010).

However in terms of outcome, it might (politely) be suggested to Tooby and Cosmides that they are being somewhat naïve in assuming that the social sciences (and the humanities), as they are currently constituted, will simply accept Tooby and Cosmides' profound criticisms on purely intellectual grounds and then transform themselves in the image of evolutionary psychology by their own volition. More likely to be the case is that the mainstream social sciences (and the humanities) will either ignore these criticisms for as long as possible or they will advance counterarguments against evolutionary psychology, or (most likely) a combination of both of these strategies. As the title of the book *Alas, Poor Darwin: Arguments Against Evolutionary Psychology* suggests, the latter strategy has been deployed for some time now.

Moreover, as this entry has suggested, there are strong reasons why the erroneous SSSM has prevailed for so long in academia, such as the political agenda of much of the contemporary social sciences (and the humanities), which dovetails closely with the “blank slate”/infinite malleability assumptions of human nature and the *Homo sapiens* brain that are promoted within the SSSM.

As has been outlined by other scholars, scientific revolutions do not often proceed purely through victories in rational debate. Holders of older, outdated views often cling to their pre-existing ideas until they die, regardless of the validity of their arguments, a good example of

this being Albert Einstein's opposition to quantum mechanics. In such cases, the new intellectual order only triumphs completely when the last of the old guard have passed away. Since there are very large numbers of individuals currently working in the mainstream social sciences, it might, therefore, take some considerable time for the Darwinian revolution to take full hold in this realm.

Short-term mating strategies

Definition

Defining and outlining short-term mating.

Introduction

When researching mating behaviour, it is important to take mating strategies into consideration. It is evident that men and women seek a variety of characteristics when seeking a short-term or long-term mate, which are often guided by parental investment (Trivers 1972) and sexual selection. Wiederman and Dubois (1998) suggest that short-term mating refers to choosing and engaging in sexual activity with someone on a short-term basis, where the probability of cementing a long-term relationship is relatively low. In contrast, “long-term mating implies increased probability that the relationship will be long-lasting” (p. 154).

According to sexual strategy theory (Buss and Schmitt 1993), men and women seek traits, depending on whether they are engaging in short-term or long-term mating. For example, when seeking short-term mates, women typically seek status indicating traits which signal genetic quality, such as physical attractiveness and strength (Takahashi et al. 2006). One potential reason for choosing mates of genetic quality is that women have a stronger chance of producing

offspring who possess traits of genetic quality, thus increasing their offspring’s future reproductive success.

Both sexes value attractiveness, especially when seeking short-term mating opportunities, placing a great emphasis on body shape and size because they signal good health and genetic quality. Women may also view short-term mating as an opportunity to gain a long-term mate, choosing their mating partner by comparing his ability to provide resources and compare it to the quality of others. When seeking short-term and long-term mates, men typically seek youthful, attractive women, as youth is correlated with fertility (Karthikeyan and Locke 2015). These are/may be important indicators of reproductive fitness/success.

It is argued that men are more prone to engaging in short-term mating compared to women (Clark and Hatfield 1989), as men increase their reproductive successes through increased short-term sexual encounters. Furthermore, men engage in short-term mating as they have less to invest and lose compared to women (biologically speaking), thus linking to parental investment theory. Women have more to lose with short-term mating encounters due to risk of unwanted pregnancy, rearing offspring and an arguably damaged sexual reputation, deterring potential mates and increasing paternal uncertainty. As a result, our mate preferences can be guided by whether we seek short- or long-term mates.

Short-term mate seeking may provide women with an opportunity to assess a male’s ambition to succeed which may be a cue to earning potential in the future (Wilbur and Campbell 2010). In support, previous research has found that women value ambition when seeking short-term partners, which may be indicative of status and wealth (Wilbur and Campbell 2010) all of which can be explained by sexual selection theory and parental investment.

According to parental investment theory, women should exert more choice when selecting a mate. In support, men, especially when seeking short-term mates, are less choosy than women (Bhogal et al. *in press*). This may be because when engaging in short-term mating, men may be seeking sexual access and evaluating

physical cues related to sexual value, instead of long-term commitment. There are benefits in engaging in short- and long-term mating. For example, Margana et al. (2019) found that women were attracted to heroic and altruistic men for long-term relationships compared to short-term relationships.

A woman nurtures a child through breastfeeding, rearing, and nurturing. As a result, the secondary sexual characteristics evolved for men and women will naturally vary, with a male's resources and commitment valued by a woman and a woman's fertility and attractiveness valued by men. This may be a reason as to why physical attractiveness may be a marker of genetic quality, relating to the "sexy son hypothesis" which suggests that females choose attractive males in order to produce attractive offspring, which in turn leads to the child having increased reproductive successes and passing on their genes successfully. This could relate to several behavioral and physical traits. Physical attractiveness offers heritable benefits, assists in increasing the survival of good genes, and offers an array of advantages throughout one's life. By choosing a mate with heritable, quality traits, a female provides her child with a survival and reproductive advantage over others who do not possess these traits. In support, recent evidence suggests that women find physically attractive men more desirable than men of low attractiveness (Margana et al. 2019).

The benefits for women who engage in short-term mating may be gaining resources or producing offspring of a high genetic quality (Cashdan 1993). This argument suggests that women value attributes which relate to genetic quality, such as height, health, and masculinity, linking to the finding mentioned previously that women do also value physical attractiveness. This creates a market style environment which gives rise to competition for mates and gaining access to the highest quality mates available, creating a perfect environment for sexual selection to take its course.

Men of high mate value (those who are more physically attractive, are strong and have status/resources) invest more in gaining as many short-term mates as possible, whereas males with lower mate value invest more in long-term relationships.

Conclusion

In summary, short-term mating refers to mating behaviour which typically occurs without the intention of cementing a long-term relationship. As discussed, short-term mating involves using mating strategies that differ compared to when engaging in long-term mating, evident by sexual strategies theory.

Siblicide

Definition

The killing of one sibling by another.

Introduction

Siblicide is the most extreme form of sibling conflict. Although somewhat rare in humans, siblicide is much more common in other animal species (e.g., various avian species). Sibling conflict (even though it may be intense at times) is considered to be a normal part of development, and the developmental literature indicates that most siblings outgrow these patterns of intense jealousy and conflict when they reach adulthood and move away from their parents' home (Buhrmester and Furman 1990). Siblicide, however, is most likely to occur in early and middle adulthood (Underwood and Patch 1999) when this is not the case – that is, when adult siblings continue to live together (Ewing 1997).

Relative to other types of familial homicides (e.g., spousal homicides, filicides – parents killing their offspring, and parricides – children killing their parents), siblicide is the rarest form of family homicide (Diem and Pizarro 2010). Investigations of siblicide in both US and Canadian samples indicate that siblicides account for approximately 1.4–2 % of all homicides (e.g., Daly and Wilson 1988). The most common form of siblicide is brother-killing-brother with over 70 % of siblicides fitting this pattern (Underwood and Patch 1999). Consistent with an evolutionary perspective, when siblicides do occur, the cause has typically been found to be competition over limited resources (Daly and Wilson 1988; Pollet and Hoben 2011). In addition, the fact that siblicide is rare among humans is consistent with predictions from Hamilton's kin selection theory (1964) that it would be more likely for siblings to join forces and cooperate with each other against nonkin versus kill each other. Siblicides do still occur, though, so the question becomes why? What factors influence the likelihood that one sibling will kill another versus form an alliance with their sibling?

Factors that Influence the Likelihood of Siblicide

Several proximate as well as ultimate factors have been identified as influencing the likelihood

that one sibling would kill another. Some of the proximate factors include poverty, mental illness, unresolved conflicts, stress, and substance abuse (Diem and Pizarro 2010; Ewing 1997). From an evolutionary perspective, ultimate factors include age (or birth order), sex, and degree of relatedness.

Age and Birth Order. As mentioned above, siblicide is most likely to occur in early and middle adulthood, not in adolescence as one might expect (Underwood and Patch 1999). Analysis of siblicide data in the USA from 1993 to 1995 found the mean age of siblicide perpetrators is 34.4 years of age, the mean age of siblicide victims is 33.3 years of age, and overall that 86 % of siblicide victims are between the ages of 20 and 59 (Underwood and Patch 1999). Crossculturally it also appears to be more likely for a younger sibling to kill an older sibling than the other way around (Daly et al. 2001; Underwood and Patch 1999). Furthermore, siblicides are most likely to occur between siblings who are within 5 years of age of each other. Interesting, the pattern of juvenile siblicides (in which both victim and perpetrator are under the age of 18) is reversed with older siblings being more likely to kill their younger sibling. One study found this opposite pattern of juvenile siblicide in 65 % of juvenile siblicide cases (Daly et al. 2001).

Circumstances that lead a younger sibling to kill an older sibling seem to involve a power struggle in which the older sibling attempts to assert his own dominance in the relationship (e.g., with regard to familial property, money, and entitlement) and the younger sibling defies the older sibling's presumed authority (Daly et al. 2001). This pattern was found crossculturally across societies in which older siblings are given privileged status over younger siblings (e.g., Japanese, American, British, Canadian, and tribal societies; Daly et al. 2001).

Sex. Analysis of siblicide data indicates that 76.1 % of siblicides have been brother-killing-brother, 11.9 % have been brother-killing-sister, 8.2 % have been sister-killing-brother, and 3.9 % have been sister-killing-sister (Underwood and Patch 1999). This pattern has been consistent across several studies (e.g., Daly et al. 2001).

This is consistent with the expectation that same-sex siblings would have more intense conflict given they would be more likely to be competing over the same parental resources and attention, which would be expected to increase as siblings are closer in age.

Degree of Relatedness. Perhaps due to its infrequency as well as the lack of clear relatedness information in many of the available homicide data sets, the effect of relatedness on siblicide has been greatly understudied and therefore is not well understood. From an evolutionary perspective, one would expect the likelihood of one sibling killing another would be moderated by their degree of relatedness, such that less relatedness would lead to more conflict and more incidence of siblicide. That is, fewer incidents of siblicide among full siblings (relative to half-siblings and step-siblings) would be expected. One study that investigated the relationship between relatedness and siblicide, however, found evidence inconsistent with that prediction. Specifically, findings indicated that approximately 93 % of siblicides involved full siblings, 4 % involved half-siblings, and 3 % involved step-siblings (Russell et al. 2007). However, consistent with evidence that step-parents use more brutal methods to murder their children than do biological parents (Daly and Wilson 1994), the siblicide data suggested that siblicides involving half-siblings and step-siblings were more brutal than those involving full siblings. Overall, the question of the relationship between relatedness and siblicide is still largely unanswered and more studies in this area are needed.

Conclusion

Although siblicide in humans is quite rare relative to nonhuman species, the underlying cause seems to be availability of (and conflict over) resources. Specifically, among humans, siblicides tend to be committed by adult siblings (with the younger sibling killing an older sibling) who are still living together in intense competition over parental resources, status, and power. Males are more

likely to be both victims and perpetrators of siblicide, whereas females are more likely to be victims. One key factor that requires more investigation is the effect of relatedness on human siblicide.

Definition

Competition and animosity among siblings.

Introduction

Sibling relationships in humans are often marked by feelings of love as well as hate for each other, providing a quintessential example of ambivalent relationships. In fact, relative to other types of familial violence (e.g., spousal and parent–child violence), sibling violence is the most common form of nonlethal familial violence (Wiehe 1997).

Although this conflict and animosity between siblings can be quite intense at times, it is typically considered to be a normal part of development (Cicirelli 1995). As such, sibling conflict has been linked to both potential benefits and costs in terms of psychosocial and cognitive development. For example, potential benefits identified include the development of greater empathy and perspective taking (Dunn and Brown 1994) as well as practice with social negotiation leading to greater conflict resolution and problem-solving abilities (Campione-Barr and Smetana 2010). Potential costs have been found to stem from especially intense and unresolved sibling conflict which may lead to a host of behavioral, psychological, and academic problems by early-mid adolescence (e.g., delinquent behavior and peer rejection; Cohen 2004). Although sibicide is rare in human siblings, extreme cases of sibling conflict can lead to the death of one sibling at the hands of another.

Sibling Conflict Theory: Predicting Likelihood of Competition Versus Cooperation

From an evolutionary perspective, sibling conflict would arise from competition over limited resources. For human siblings, this would mean rivalry over limited parental resources. Whereas across our evolutionary past, those resources may have been limited food and basic resources such as shelter; in modern societies, parental resources would involve time, attention, and money given to one's self versus their sibling(s). So, while factors such as availability of resources and number of siblings (i.e., number of potential competitors for those limited resources) would predict competition, what factors would predict the likelihood of cooperation among siblings (or other kin)? This question was difficult to answer from an evolutionary perspective until Hamilton (1964) proposed *kin selection theory* as well as the concept of *inclusive fitness*. According to Hamilton (1964), fitness not only involves one's own successful survival and reproduction (i.e., transmitting one's genes to subsequent generations) but

also the survival and successful reproduction of genetically related individuals. According to this theory, individuals may indirectly increase their own inclusive fitness by directing altruistic behavior towards their kin. According to *Hamilton's rule* (1964), the amount of altruism directed at one's kin is a function of whether the degree of relatedness and the potential fitness benefit the other person would receive outweighs the potential fitness cost to oneself (i.e., $r * b > c$). Therefore, we would expect to see greater cooperation (and less conflict) among individuals with greater genetic relatedness (e.g., full siblings vs. half siblings vs. nonbiologically related siblings). This prediction has been supported by evidence demonstrating adults report greater feelings of subjective closeness to closer related kin (e.g., sibling vs. cousin) as well as to kin relative to nonkin (Neyer and Lang 2003).

Observations of sibling conflict, including suggestions that it is a normal part of development such that animosity towards one's siblings should be expected, however would suggest that the relationship between genetic relatedness and cooperation (or altruism) is not that straightforward. *Parent-offspring conflict theory* (Trivers 1974) provides another example of how genetic relatedness does not always predict common interests nor altruistic behavior directed toward one another. Specifically, the genetic interests of parents and their offspring are often not identical and each will be selected to manipulate the other in order to suit their own genetic interests. While the offspring will want more parental investment (e.g., time, food, etc.), the more a parent invests in any one offspring, the less s/he may invest in other offspring. According to *parental investment theory* (Trivers 1972), how much a parent invests in any one offspring depends on the amount of resources available to the parent, the quality of the offspring, as well as their other offspring (current as well as potential future offspring). Assuming availability of resources and equal quality offspring, a prediction of this theory is that parents would invest equally in their offspring. Sibling conflict could still arise, however, because offspring are more closely genetically related to themselves than to their siblings and so would be

motivated to compete with their siblings for a greater share of the resources.

Evidence suggests that family size does predict levels of sibling conflict. Specifically, it has been found that although more siblings are associated with more overall incidents of sibling conflict, fewer siblings are associated with more severe acts of violence (Straus et al. 2006). Studies which have investigated proximate explanations of sibling conflict found the most commonly cited sources of conflict (cited by both older and younger siblings) involved issues of relative power, self-interest (e.g., sharing of personal items), violation of rules (e.g., perceived immaturity and inappropriate behavior), as well as interests outside the family (McGuire et al. 2000). Across different ages from toddlerhood through adolescence, the most commonly cited source of conflict (in terms of both frequency as well as intensity) has been the sharing of personal space and possessions, while the least cited source of conflict has been competition over parental attention (Campione-Barr and Smetana 2010; Dunn and Munn 1987; McGuire et al. 2000; Steinmetz 1977).

Factors That Affect the Prevalence and Intensity of Sibling Conflict

Some proximate and ultimate factors have been found to influence both the prevalence as well as the intensity of sibling conflict. Proximate factors include temperament and differential parental treatment and ultimate factors include sex, relatedness, birth order, and birth spacing (including length of coresidence).

Temperament. Brody and colleagues (1987) found that differences in temperament of younger children – or personality differences in older children – are associated with sibling conflict. Specifically, it was found that higher levels of activity and emotional intensity lead to greater levels of aggression (and less prosocial behavior) directed toward their sibling. For female sibling pairs, this was true when both the older and younger sisters had higher levels of activity and emotional intensity. For male sibling pairs, greater levels of

conflict were found when the younger brother had higher levels of activity and the older brother had higher levels of emotional intensity. Furthermore, in the male sibling pairs, it was found that any aggressive behavior from the younger brother led to reciprocated aggression from the older brother. Although temperamental differences predicted frequency and intensity of sibling conflict, overall the greatest conflict was observed among siblings in which both possessed traits of higher activity and/or emotional intensity.

Differential parental treatment. Evidence suggests that children as young as 3 years of age actively monitor their siblings' relationships with their parents relative to their own and are sensitive to differences in parental treatment between themselves and their siblings (Dunn and Munn 1985). Perception of differential parental treatment between siblings has been associated with greater levels of sibling conflict (Brody et al. 1992a, b). Shanahan and colleagues (2008) found that the effect of perceived differential treatment on the sibling relationship is moderated by birth order. Specifically, firstborn children who perceive more favorable maternal treatment directed at their younger sibling tend to withdraw from the relationship; whereas secondborn children tend to respond by directing more aggression to the favored older sibling.

Sex. Evidence suggests that not only do boys have more conflict with their siblings than do girls (Brody et al. 1985) but boys also are more violent toward their siblings than are girls with the highest level of sibling violence occurring among brothers (Straus et al. 2006). Boys tend to be less violent with sisters than with brothers. Although across all ages girls are less likely to use physical violence relative to boys, girls with brothers tend to be more violent than girls with sisters. While not physically violent, opposite-sex siblings have more conflict than same-sex siblings (Campione-Barr and Smetana 2010).

Relatedness. Surprisingly, despite the already mentioned theoretical relevance of genetic relatedness to the question of sibling conflict, the effect of relatedness on the frequency and intensity of sibling conflict has been understudied in human research. Instead, studies investigating the effect

of relatedness on sibling relationships have mainly focused on the solidarity of sibships finding a preference for full siblings over half-siblings (Jankowiak and Diderich 2000), greater interaction and contact as a function of closer relatedness (Pollet 2007; White and Riedmann 1992), as well as higher levels of cooperation and closer relationships between monozygotic twins than dizygotic twins (Segal 2005). One recent study investigated the effect of relatedness between siblings on the level of sibling conflict and found greatest levels of conflict between nonbiological siblings, followed by full siblings, with the lowest level of conflict between half-siblings (Salmon and Hehman 2015). These findings were not consistent with predictions that full siblings would have the least amount of conflict nor were they consistent with findings from the sibling solidarity research. The discrepancy in findings regarding the effect of relatedness on solidarity versus conflict may suggest that different mechanisms underlie those two relationship outcomes such that relatedness does not decrease conflict as it increases solidarity (at least when it comes to conflict between full vs. half-siblings). Future research is needed to explore possible explanations for the differences found with regard to the effect of relatedness on sibling relationships.

Birth order. Firstborns are more likely to invest in their siblings as well as maintain closer contact relative to laterborns (Pollet and Nettle 2009). Middleborns tend to have less positive perceptions of their parents relative to first- and lastborns and prefer to have close relationships with a nonrelated friend versus kin (Salmon 2003). There also appear to be birth order effects on the sources of sibling conflict with older siblings citing the younger sibling's immaturity as a source of the conflict and younger siblings citing rejection and aggression from the older sibling as a source of the conflict (Buhrmester and Furman 1990).

Birth spacing and length of coresidence. Greater levels of conflict have been observed in siblings who are closer in age, with the greatest level of conflict occurring between siblings who are within 2 years of age of each other and presumably would be competing over similar

parental resources as they would be in similar stages of development with similar needs (Cicirelli 1995; Pollet 2007). Evidence suggests that birth interval does influence the level of conflict with longer birth intervals (i.e., greater spacing) associated with less conflict (Salmon and Hehman 2015). Length of coresidence could also affect levels of sibling conflict with longer duration of coresidence perhaps contributing to a greater sense of solidarity and sibship, hence less conflict. To date, only one study has investigated the role of coresidence on levels of sibling conflict, but contrary to what was expected it found that less coresidency was associated with less conflict (Salmon and Hehman 2015). This could be simply due to less opportunity for conflict (as well as solidarity) to arise with less coresidency, but further research is needed in this area.

Conclusion

Given that sibling relationships are some of the most enduring relationships across the life span (Cicirelli 1995), there is great potential for competition as well as cooperation among siblings. Proximate factors that lead to increased sibling conflict include temperament (with greater conflict among sibling pairs in which at least one has higher levels of activity and/or emotional intensity) as well as differential parental treatment (with greater recognition of differential parental treatment leading to greater conflict). Ultimate factors that lead to increased sibling conflict include sex (with boys being more aggressive towards their siblings than girls and brother-brother pairs experiencing the greatest levels of conflict), relatedness (with greater conflict between nonbiological siblings vs. related siblings), birth order (with birth order affecting perception of the source of the conflict), and birth spacing (with greater conflict between siblings who are closer in age). The effects of relatedness and length of coresidence on the frequency and intensity of sibling conflict is still understudied and needs further investigation to fully understand how those factors influence sibling relationships.

Definition

Research designs that use sibling comparisons to infer genetic and environmental contributions to phenotypes.

Introduction

Sibling studies are a class of research methodologies that compare siblings within and/or between families. A genetically informed subtype of sibling study utilizes information about genetic relatedness between siblings and principals of genetic inheritance to infer both environmental and genetic influences on phenotypes. Genetically informed sibling studies include monozygotic (MZ) and dizygotic twins (DZ), nontwin full siblings, half-siblings, and adopted siblings.

Twin Designs

Basic twin studies compare concordance or correlations between pairs of MZ and DZ twins to evaluate trait heritability. Monozygotic twins are genetically identical (i.e., identical twins) whereas dizygotic twins share only 50 % of their genes, on average, and are genetically the same as full siblings (i.e., fraternal twins). Within-pair correlations between MZ and DZ twins provide information about the relative contributions of additive genetic, shared environment, and

nonshared environmental influences through statistical modeling. Twin studies operate under a number of statistical and conceptual assumptions that are generally robust against violations (Barnes et al. 2014). Classic twin studies can also include other sibling types, such as full, half-, and stepsiblings (e.g., McGuire et al. 1994; O'Connor et al. 1995). Additionally, more complex research designs have been developed based on twin methodology such as twins reared apart (Bouchard et al. 1990), the Children of Twins (CoT; D'Onofrio et al. 2003; Silberg and Eaves 2004), and Extended Children of Twins designs (ECOT; Narusyte et al. 2008; see ► “Twin Studies”)

Differential Sibling Exposure Design

Unlike twin designs that compare within-twin correlations between MZ and DZ twins (and other siblings), the differential sibling exposure design relies exclusively on full siblings reared in the same family. This method is a form of matched-pair design where siblings are effectively matched on potentially important and unmeasured factors such as culture, socioeconomic status, and religion by virtue of developing within the same household. Consequent within-family sibling analyses are therefore adjusted for these kind of family-wide confounds. Importantly, this within-family sibling design also controls for genetic liability (through randomization), since genetic effects are assumed to vary randomly as a function of birth order (i.e., the alleles of parents' genes are randomly distributed across siblings through meiosis). In other words, because there is no reason to suspect that genetic liability for anything will vary systematically with birth order, in sufficiently large samples of sibling pairs, random deviations in genetic liability are averaged out.

Measuring sibling differences in environmental exposures is key to the differential sibling exposure design. For example, this design has been used to examine the effects of father absence and paternal characteristics on adolescent girls' age at menarche and risky sexual behavior.

Consider an older and younger sister whose parents divorced when the older daughter was 9 and the younger daughter was 3 years old. In this scenario, the older daughter will have been exposed to a father present household for 6 additional years compared to her younger sister. The older and younger sister, therefore, differ in their exposure dosage to a father absent household and associated paternal characteristics (Tither and Ellis 2008; Ellis et al. 2012). Because the research design controls for both genetic liability and family-wide environmental confounds, this design is a causally informative method for evaluating the impact of differential exposure to fathers on sisters' developmental outcomes (in this case reproductive functioning). This design could potentially be used to examine differences between siblings in any trait as a result of differential environmental exposures that were not caused or influenced by the siblings themselves (e.g., differential prenatal exposure to smoking; D'Onofrio et al. 2012).

The differential sibling exposure design rests on a number of assumptions. These include that the siblings are full biological sibling pairs (same mother, same father), that the candidate environmental factor differs across siblings, that differential exposure to the candidate environmental factor was not influenced by either of the siblings' characteristics or behavior (as occurs with self-selection into environments), that one sibling does not influence the other sibling's exposure to the candidate environmental factor, that the differential environmental exposure was large enough to influence the target phenotypic outcome, and that there was a large enough number of sibling pairs to randomize genetic effects across birth order.

An additional assumption common to this and other sibling designs is generalizability. Generalizability in sibling studies stipulate that the findings derived from sibling comparisons apply to individuals. The generalizability assumption may be particularly important for twin studies given the uniqueness of twin rearing experiences relative to singletons. However, there demonstrated similarities on a number behavioral and developmental outcomes between twins and singletons (Barnes and Boutwell 2013).

Conclusion

Sibling studies are a collection of research designs useful for teasing apart genetic and environmental influences on behavior and other outcomes. Sibling designs utilize similarities and differences in genetic relatedness within and/or between families to draw conclusion about the relative contributions of genes and environments. These family-based methodologies may include monozygotic twins, dizygotic twins, full siblings, half-siblings, stepsiblings, and/or adopted siblings. Twin studies are a common genetically informed sibling design although there are many other sibling designs that permit inferences about genetic and environmental contributions, such as the differential sibling exposure design.

Definition

Individuals born of the same mother and father.

Introduction

The term *sibling* refers to the biological relationship between two individuals who share the same biological mother and biological father. This term is often qualified with the adjective *full* (i.e., *full sibling*) to differentiate between other types of sibling relationships such as *half sibling* – which indicates that two individuals have only one biological parent in common – and *step sibling* – which indicates that two individuals do not share the same biological mother nor the same biological father. Step siblings are labeled as such because one of the individuals' parents (i.e., the mother or the father) has courted and married either the mother or the father of the second individual.

Sibling relationships have often been the subject of study in evolutionary psychology. In fact, many evolutionary psychological theories have accounted for the variance in behavior between siblings, as well as the differences in behavior between full siblings, half siblings, and step siblings. Evolutionary psychologists have been able to adequately explain the variance in altruism between siblings (Burnstein et al. 1994; Fitzgerald and Colarelli 2009), the reasons for sibling rivalry (Michalski and Euler 2008), and personality differences in siblings based on the order of their birth (Sulloway 1995, 1996). Each of these theories will be briefly addressed in this entry.

Kin Selection Theory

Kin selection theory accounts for altruistic actions between kin members as a means of maintaining and/or improving the reproductive success of one's genes (Burnstein et al. 1994; Fitzgerald and Colarelli 2009; Hamilton 1964). Theoretically, if one possesses a gene that is responsible for motivating life-threatening altruistic behavior

(e.g., running into a burning house to save someone, willingness to donate an organ, etc.), that particular gene stands a greater chance of survival and reproduction if it motivates altruistic behavior toward one's kin (i.e., individuals who have a greater chance of also possessing a copy of this altruism allele). Therefore, one may be more inclined to risk his/her life to save an individual if the recipient of this altruistic act is closely related to the altruist (Burnstein et al. 1994; Hamilton 1964).

Because individuals receive half of their genes from each parent, and full siblings share both biological parents, there is an approximate 50% probability of both siblings possessing the same gene – in this case, the gene that is responsible for altruistic behavior. This is often referred to as $r = 0.50$, in which r refers to the genetic relatedness between the two individuals (Hamilton 1964). Half siblings, only sharing one biological parent, possess $r = 0.25$ (an approximate 25% probability of both siblings possessing the same gene), and step siblings do not share any biological parents, so they possess $r = 0$ (Burnstein et al. 1994; Fitzgerald and Colarelli 2009; Hamilton 1964).

If kin selection theory is true, then studies should show an increased likelihood of life-threatening altruistic behavior between individuals of greater genetic relation. In fact, data from several studies have found support for this claim. Individuals are significantly more likely to risk their lives to save full siblings over half siblings (Fitzgerald and Colarelli 2009) and step siblings (Burnstein et al. 1994).

Sibling Rivalry

While full siblings share $r = 0.50$ and are therefore more likely to risk their lives to save each other, research into sibling rivalry has indicated that individuals may also place greater emphasis on one's own survival – at least in regard to parental resource acquisition – than a sibling's survival (Michalski and Euler 2008). Survival during youth is often influenced by the reception of parental resources – these resources refer not

only to food but emotional warmth and security as well.

Because parental resources are finite, siblings may compete with their fellow siblings for these parental resources. These competitive behaviors may manifest in the form of one sibling exaggerating his/her need for parental resources, even at the expense of another sibling (Michalski and Euler 2008). Dunn and Kenrick (1982) found that children may engage in less developmentally mature behaviors (e.g., acting significantly younger than their chronological age) once a younger sibling is born. This behavioral regression is believed to occur as a means of diverting parental resources to one's self instead of to the newborn sibling.

Birth Order

Birth order refers to the chronological position, relative to one's siblings, in which one was born. For example, a firstborn child refers to an individual who was born before all other siblings. A later-born child refers to an individual who was born after one or more siblings. Many individuals have theorized that differences in birth order – due to variance in selective pressure from the environment, such as parental care and attention – may lead to differences in personality between siblings (Sulloway 1995, 1996). More than 200 studies have been conducted on this subject.

Frank Sulloway theorized that birth order may account for many differences in the five-factor model of personality – extraversion, conscientiousness, agreeableness, neuroticism, and openness (McCrae and Costa 1987) – between siblings. According to birth order theory, firstborn children will possess higher levels of extraversion, conscientiousness, and neuroticism than their later-born siblings. Firstborn children will also possess lower levels of agreeableness and openness than their later-born siblings.

Sulloway's (1995) meta-analysis of 196 birth order studies found support for this relationship

between birth order and the five-factor model of personality. Specifically, firstborn siblings were more talkative, more assertive, more responsible, more organized, more achievement-oriented, more anxious, more fearful, and more neurotic than their later-born siblings – indicating higher levels of extraversion, conscientiousness, and neuroticism. Also, firstborns were less approachable, less easygoing, less independent, and more traditional than their later-born siblings – indicating lower levels of agreeableness and openness. However, the relationship between birth order and personality is quite controversial. While many studies have found support for the above-mentioned relationships, many other scientists have been unable to replicate similar findings (Beer and Horn 2000; Freese et al. 1999).

Conclusion

Evolutionary psychology has provided many theories to account for sibling cooperation, rivalry, and differences in personality. While the three theories discussed in this entry – kin selection theory, sibling rivalry, and birth order – provide supported explanations for behavior between siblings, they are not the only theories that account for sibling behavior, nor do they account for all sibling behavior. Evolutionary psychologists continue to conduct research and evaluate all theories related to sibling relationships and behavior.

Definition

Siblings are individuals with mutual parents. Full siblings share both parents, while half-siblings

only share one parent. In consequence, on average 50% of the segregating genes of full siblings are same, whereas for half-siblings the number is 25%. According to kinship selection theory, siblings are expected to behave altruistically toward each other, because the mutual genes imply inclusive fitness benefits of such behavior. However, siblings are also expected to compete for parental resources. The opposing forces of cooperation and conflict strongly define sibling relations.

Introduction

Siblings shape each other's childhood environments significantly, and in a way, each child is born into a different family. While altruistic actions are expected from siblings due to mutual genes, in infancy siblings mostly represent competition for parental resources. A firstborn receives a hundred percent of parental investment for the first few years of life, and the last-born's infancy is not interrupted by new babies. The middle-born, however, have to share parental investment throughout childhood. The number and characteristics of the existing children in the family provide a background for individual development. Accordingly, the existence of siblings, in general, and more specifically birth order effects on developmental outcomes, well-being, and personality have been studied quite extensively from an evolutionary viewpoint.

Birth Order and Development

The sheer existence or nonexistence of siblings profoundly modifies the developmental environment of an individual. A large body of literature associates siblings with negative outcomes. The number of siblings is inversely related to academic achievement and adulthood income in Western contemporary societies and to child survival in preindustrial societies (Lawson et al. 2012; Steelman et al. 2002). This is assumed to be the consequence of parental quality–quantity trade-off: with limited parental resources, each additional child reduces investment in any one

child (see, e.g., Gillespie et al. 2008). Nevertheless, the effects of siblings vary substantially with ordinal position in the sibship. There is an indisputable “firstborn advantage” in almost every outcome that has been studied so far, from reproductive success to education (see, e.g., Steelman et al. 2002). Later-borns are suffering more, while firstborns usually fare equally well as only children.

Some studies suggest that middle-borns differ from other children by, for example, being emotionally less attached to the family (Salmon and Daly 1998). It is hypothesized that such a pattern is indicative of parental investment: firstborns receive exclusive parental investment before other children are born and afterward may receive disproportionate amounts of investment because they have a higher reproductive value (i.e., they have survived some or most of the potential hazards causing child mortality and are closer to starting reproduction; see Sulloway 1996). Last-borns, in turn, as the last baby of the family, receive more investment from the mother in infancy and are usually the last ones to leave the nest. Conversely, middle-borns are forced to share parental investment throughout childhood (Sulloway 1996). However, many studies have not found any distinct middle-born effects on developmental or reproductive outcomes, and their existence is currently under dispute.

Sibling Relationship Quality

As siblings represent less parental resources directed to any one child, the resulting competition for parental resources is likely to cause conflicts among siblings. Accordingly, substantial amounts of sibling bullying are not uncommon in sibling relationships (Wolke et al. 2015). As later-born siblings are more disadvantaged by having siblings than firstborns, it might be hypothesized that later-borns compete more and thus have less positive relationships with siblings than firstborns. Indeed, this seems to be the case, as older siblings, in general, and firstborns, specifically, are more likely to describe their sibling relationships as very good (e.g., Pollet and Nettle

2009). Pollet and Nettle (2009) further hypothesize that the better quality of sibling relationships reported by firstborns is related to them potentially gaining larger inclusive fitness benefits from altruistic behaviors toward siblings in adulthood. Having reached maturity, and started reproduction, a younger individual always has a higher reproductive value than an older one, i.e., more expected years to procreate. As firstborns are always older than later-borns, they benefit more from investing in their younger siblings than vice versa. The existence of older pre-reproductive siblings, actually, seems to be associated with higher survival of younger siblings (Sear and Mace 2008). This possibly reflects altruistic childcare of younger siblings, as older siblings function as “helpers at the nest.”

Niche Picking

Ordinal position in the sibship could also be related to personal characteristics such as personality and ambition. Frank Sulloway (1996) first hypothesized that siblings influence each other’s personality in ways that can be understood from an evolutionary viewpoint. Firstborns, in general, would benefit from being more assertive than later-borns. This is because firstborns are by definition older, bigger, and stronger than others and therefore more readily gain benefits from behaving dominantly. In addition, firstborns are hypothesized to be more conscientious than other members of the sibship, because they often take on the role of a “surrogate parent,” i.e., aid parents in caring for later-born siblings. Firstborns, in a way, can afford to behave altruistically toward siblings, because they generally receive more parental investment. According to Sulloway’s theory, other children adjust to the personality characteristics of existing children with a process called de-identification or niche picking. Being dissimilar than other members of the sibship allegedly decreases competition (Sulloway 1996).

Empirically, birth order effects on personality have been vastly studied. The results, however, are very mixed. Some studies find patterns as hypothesized by Sulloway, with firstborns being

more dominant or conscientious than later-borns (e.g., Paulhus et al. 1999), but many do not (e.g., Rohrer et al. 2015). In the absence of a comprehensive meta-analysis, the jury is still very much out. However, Sulloway's theory on niche picking points out the evolutionary uniqueness of the family environment and sibling constellation for its individual members.

Conclusions

Siblings face the opposing evolutionary forces of competition and cooperation in their interactions with each other. These forces are not, however, met similarly by all members of the sibship. The existing numbers and qualities of children in the family provide a unique environment for each successive child. This environment shapes the characteristics of the members of the sibship and interactions between them, as each individual tries to find a niche in which fitness is maximized.

Definition

Siblings are individuals who share parents. Full siblings share both the mother and the father, while half-siblings share only one parent. Through mutual parents, siblings are genetically related to each other. On average, 50% of the segregating genes of full siblings are same, although the range, in principle, is from 0 to 100%. Half-siblings, on average, have 25% of

their segregating genes in common. Stepsiblings are individuals whose parents are in a romantic relationship and who usually live in the same household, but are not genetically related to each other. This entry concentrates on full and half-siblings. Siblings are assumed to share mutual goals through their mutual genes and therefore expected to behave altruistically toward each other. On the other hand, siblings are expected to compete for parental resources.

Introduction

A majority of humans grow up with a sibling or siblings, and relationships with siblings often-times are the longest relationships in an individual's life course. Full siblings share, on average, 50% of their segregating genes, while half-siblings, on average, share 25%. According to the inclusive fitness theory, alternatively called the kin selection hypothesis, genetically related individuals have an incentive to behave altruistically toward each other. That is, helping genetically related individuals is beneficial in terms of one's own fitness, as long as the cost of the altruistic behavior is not too high. Hamilton's (1964) rule, $br > c$, where b is the fitness benefit to the recipient, c is the fitness cost to the actor, and r is the genetic relatedness between the two, sets the boundaries for altruistic behavior. Full siblings represent, alongside of parent-child relations, the greatest genetic similarity between two people, surpassed only by identical twins. Indeed, siblings do seem to help and behave altruistically toward each other (Stewart-Williams 2007), as would be expected from the Hamilton's rule.

Besides genes, siblings share parents. Human beings grow up exceptionally slowly, our big brains take a long time to develop, and human children are dependent on other people providing food and shelter many years after weaning. Although humans seem to practice a great deal of alloparenting or cooperative breeding (meaning that other people than the mother participate in taking care of the child), parents, and mothers especially, are vital for child survival (Sear and Mace 2008). In this sense, siblings represent

competition for parental investment (Trivers 1972) and, as you are always more related to yourself than to your siblings, pose a threat to your own fitness. Sibling relationships are innately characterized by these two opposing forces of altruism and competition (West et al. 2002).

Recognizing Siblings

Human individuals have no direct ways of inferring their genetic relatedness to other individuals. However, in terms of inclusive fitness, recognizing biological kin is important for altruistic behavior to be targeted appropriately. A large body of research has thus concentrated on how genetic kin recognize each other, for example, on how to confirm biological paternity. In terms of siblings, two important recognition mechanisms have been identified. Firstly, the strength of aversion to engage in sexual acts with someone signals genetic relatedness. This phenomenon, called incest aversion, was first defined by Edward Westermarck already in the early twentieth century (Westermarck 1921). Inbreeding (procreating with a genetic relative) is detrimental to fitness, and any genes aiding in avoiding it will have spread in the population. Secondly, co-residence seems to be an important factor in determining siblinghood: length of co-residence in childhood is strongly correlated with incest aversion between two individuals (Lieberman et al. 2007). Other mechanisms that play a role in sibling recognition are phenotypic resemblance and observing your biological mother breastfeed another infant. The latter mechanism, naturally, only works for older siblings, while younger siblings need to rely on other cues. Emotional closeness may function as an additional cue for recognizing siblings as targets of altruism, at least in cases where more reliable cues are missing (Bressan et al. 2009).

Conflict Among Siblings

Conflicts between siblings are extremely common – up to 40% of children report repeated

sibling bullying, that is, being a victim of or perpetrating concurrent physical or verbal aggression toward siblings (Wolke et al. 2015). Sibling rivalry is assumed to be one consequence of the so-called parent–offspring conflict (Trivers 1974). Parent–offspring conflict reflects the contradicting needs of parents and children. It is always in the offspring’s interest to extract a maximum amount of investment from the parents. For the parent, however, parental investment in one child is always traded off with investment in other children, current or potential future ones. Further, a parent may increase their own reproductive success by choosing to invest more in offspring with higher reproductive value, i.e., offspring with higher expected genetic contribution to future generations (Jeon 2008). For the child it is, naturally, utterly unbeneficial to be the one in whom parents invest less. Accordingly, it seems that sibling rivalry is increased when parents treat their children differentially. Parental differential treatment has been associated with more conflictual sibling relations in numerous studies (Volling 2003). Similarly, poorer relationships between a parent and a child are reflected in a more problematic relationship between siblings.

The amount and severity of sibling conflict is also associated with structural features of the sibling dyad, as well as personal characteristics of the siblings. The sex composition of a sibling dyad plays a role, with a dyad of two sisters being most harmonious (Volling 2003). Opposite-sex sibling dyads with an older sister are, on average, more positive and less conflictual than those with an older brother. Generally, younger siblings report less positive sibling relationships than older siblings. Studies concerning such structural features have mostly been conducted on Western industrialized societies, in the context of family sociology or psychology. The focus is generally on the well-being of the family members and, for example, implications for therapeutic interventions. Therefore it is not clear how, for example, the sex composition of the sibling dyad and its impact on the quality of the sibling relationship are related to evolutionary concepts such as parent–offspring conflict. Future research will hopefully shed more light on these matters.

Thus, existing siblings shape the developmental environment of an individual to a great extent. In addition to sex composition, birth intervals between siblings are associated with the quality of the relationship. Shorter birth intervals seem to correlate with poorer relationships (e.g., Milevsky et al. 2005). Presumably this is related to increased competition over parental investment, as two very young children impose greater challenges in caring for them. Also birth order effects on sibling relationship quality, individual development, and characteristics such as personality have been studied extensively.

With substantial divorce rates in Western societies, households with full, half-, and stepsiblings are becoming ever more common. Following Hamilton’s rule, the greater genetic similarity between full siblings compared to half-siblings would suggest greater conflicts between half-siblings: household resources are shared with a more distant relative. Perhaps somewhat surprisingly, the opposite pattern seems to be true, with conflicts between full siblings being more frequent than between half-siblings (e.g., Tanskanen et al. 2017). It has thus been suggested that as two half-siblings often have more parents (three as opposed to two in full siblings) investing in them, this would decrease the competition compared to full siblings (Tanskanen et al. 2017). In addition, it is worth remembering that Hamilton’s rule does not entail conflicts but cooperation: full siblings are expected to behave more altruistically toward each other than half-siblings. This seems to hold true, even in cases where solidarity between half-siblings is strongly culturally imposed (Bressan et al. 2009; Jankowiak and Diderich 2000), even though competition may weaken or override these altruistic impulses (West et al. 2002).

Quality–Quantity Trade-Off

While making reproductive decisions, parents are faced with a quality–quantity trade-off: the number of offspring is inversely related to the amount of resources a parent can invest in any one child. Research showing evidence of consequences of

this trade-off on children in contemporary Western societies is compelling. The number of siblings is negatively associated with individual's cognitive skills, academic performance, and adulthood income (Steelman et al. 2002). The effect of siblings on these measures is generally equal to, or even larger than, the effect of parental education, and it persists even when controlling for parental characteristics such as socioeconomic status or income. Having more siblings also seems to exert negative health effects on children, even in modern conditions with no nutritional impoverishments (Lawson and Mace 2008). On a more proximate level, it has been shown that larger number of siblings is indeed associated with lower parental investment, for example, less parental time spend in an interaction with an individual child (Lawson and Mace 2009).

Although a vast majority of research on siblings has been conducted on Western low-fertility, low-mortality populations, some studies from small-scale subsistence societies have shown similar effects. For example, in an African agropastoralist society, men with more elder brothers marry less optimally and have lower agricultural productivity and lower reproductive success (Gibson and Gurmu 2011). In pre-industrial, high-fertility, high-mortality societies, the number of siblings also significantly decreases child survival (Lawson et al. 2012). Ordinal position in the sibship also plays a role, with firstborns often faring equally well compared to only children and later-borns suffering the most. Firstborns seem to benefit from receiving undivided parental attention for the first couple of years of life. Results comparing only children with firstborns are mixed, some reporting no additional benefits of being an only child (e.g., Falbo and Polit 1986). Why only children would not benefit from monopolizing parental resources remains a puzzle to be tackled by future research.

The negative effects of having siblings seem to be more pronounced in societies where land, property, or other material assets are inherited from the parents (e.g., Gibson and Gurmu 2011). Although it is generally assumed that the trade-off between number and quality of offspring is of more importance in resource-scarce

environments, it seems that better environmental or material conditions actually might steepen the trade-off (e.g., Lawson and Mace 2008, 2009). This pattern has been observed both in developing and industrialized societies. As environmental and/or economic conditions pose less restrictions to child survival, development, and well-being, the maximum amount of parental investment still expected to be beneficial to fitness is increased (e.g., Quinlan 2007). And as parental investment increases, so will the competition over those investments between siblings increase.

Cooperation Between Siblings

Research on siblings has mainly concentrated on conflicts and competition, and less is known about altruistic behavior between siblings. However, despite the overall negative effects of having (especially older) siblings on health, survival, and educational attainment, it seems that siblings may also function as “helpers at the nest.” When siblings are sufficiently old as not to compete for parental resources as much as in early childhood, but still pre-reproductive, their presence seems to improve the survival of younger siblings and increase mother's reproductive success (Sear and Mace 2008). This is especially true for older sisters. In hunter-gatherers, older pre-reproductive siblings seem to provide direct child care as well as nutritional resources to the family. In addition, while a larger number of siblings is detrimental to the “quality” of children in postindustrial societies, it does not seem to translate into poorer reproductive success of those children (Goodman et al. 2012). On the contrary, number of siblings positively correlates with the number of one's own children in low-fertility and low-mortality conditions. In other words, in terms of ultimate fitness, the negative effects of siblings may not be detrimental, at least in affluent environmental conditions.

People express willingness to behave more altruistically toward siblings than other close, non-kin acquaintances (Stewart-Williams 2007). This difference in willingness to engage in altruistic behavior increases as the altruistic behavior

becomes more costly. Siblings also do not expect reciprocity in or gratitude from altruistic behavior toward each other, whereas both are expected from altruistic behaviors toward close friends (Rotkirch et al. 2014). Altruistic behavior in sibling relationships seems to be innate, or taken for granted, while it must be earned in other close relationships.

In modern, postindustrial conditions, the effects of siblings on well-being and development have received some scholarly attention. Positive relationships with siblings (as opposed to more negative ones) seem to provide benefits for individuals, such as higher well-being or fewer internalizing and externalizing problems (Volling 2003). The causal pathways of such associations are difficult to disentangle, but the effects are most likely to be bidirectional. To what extent these positive effects of siblinghood are found in pre-industrial societies remains to be seen. On one hand, positive effects can be expected to exist in such societies as well, as sibling competition in more harsh environmental conditions seems to be less severe. On the other hand, siblings seem to pose more critical threats to individual's survival and health in such conditions, which may annihilate any positive effects of having siblings.

Sibling Relations Throughout the Life Course

Longitudinal studies on sibling relationships are scarce, and most studies on siblings have been conducted on children and adolescents. In addition, the little knowledge of sibling relations in adulthood is based on research in contemporary Western societies. Practically nothing is known of these relationships in, for example, high-fertility and high-mortality societies. However, it is expected that the nature and quality of sibling relationships change with age. Firstly, as children grow older, the need for parental investment diminishes. This should decrease sibling competition. Secondly, as siblings approach their reproductive life span or embark on parenthood, altruistic behavior toward siblings may result in greater inclusive fitness payoffs. Accordingly,

conflicts among siblings do diminish while positive affections stay the same or even increase from childhood to adolescence and early adulthood (e.g., Kim et al. 2006). However, it seems that in adults, age is inversely related to contact frequency and amount of help between siblings – while positive affections may increase (reviewed in White 2001). Being married reduces contact, perceived support, and help among elderly siblings. Somewhat surprisingly, the same applies to having children, contrary to what could be expected from Hamilton's rule. It seems that people allocate their resources toward their own children at the cost of helping siblings and their children (see also White 2001). Childless siblings, however, seem to allocate a great deal of their resources into helping their parenting siblings, especially in young adulthood (Voorpostel et al. 2007). In terms of inclusive fitness, such a pattern is expected.

Losing a spouse is related to strengthening relationships between siblings (White 2001). It seems that in an individual's social network, the innermost circle of significant others has approximately five spots (Dunbar 2003). In adulthood, these places may be filled with members of the nuclear family, but once a place is left vacant, a sibling easily fills it. Results concerning the loss of a parent are more mixed. Some studies report comparable findings to a loss of a spouse, with a parent's death increasing sibling contact (White 2001). The majority of the studies, however, seem to report decreasing emotional closeness between siblings in the face of parental death in adulthood. It may be implied that caring for elderly parents rarely provides any fitness benefits to the caregiver and causes tension in sibling relations. Nevertheless, positive relations with siblings in adulthood are associated with better mental and physical health, at least in Western industrialized societies (see Van Volkom 2006).

Conclusions

From the evolutionary perspective, siblinghood is characterized by two opposing forces: altruism driven by shared genes on the one hand and

conflict and competition driven by shared parents on the other hand. Research evidence concerning competition between siblings, for example, the negative impact of having siblings on individuals' survival, health, and socioeconomic prospects, is compelling. Less is known about altruistic behaviors between siblings. It does seem, however, that siblings behave more altruistically toward each other than toward other close, non-kin acquaintances and that altruism toward siblings is more "automatic" than other types of altruism. As competition for parental resources decreases with children growing up and potential fitness payoffs for altruistic behavior increase, sibling relationships could be expected to improve by age. With limited research on the subject, it seems, however, that the opposite might be true. However, the existence of siblings in the old age, especially if the relationship is positive, seems to have beneficial effects for mental and physical health. The evolutionary meanings and explanations of such findings are yet to be contemplated, especially because research on adult sibling relationships is currently confined to contemporary Western societies. One might only hope that these patterns are enlightened by future research.

Definition

A natural language used by the deaf that employs visual means to convey meaning.

Introduction

Sign languages are full-fledged systems of visual-gestural communication that develop spontaneously within communities of deaf people. The Ethnologue database (Lewis et al. 2016) currently includes information on 141 natural sign languages used around the world but there may be more that have not yet been described in the linguistic literature (in 2005, the same source listed only 121 sign languages). As compared to spoken languages, sign languages are still under-researched, in terms of both their grammatical and sociolinguistic properties. What leaves no doubt, though, is that they are structurally and diachronically independent of spoken languages that surround them. The fact that, for instance, American Sign Language (ASL) and British Sign Language (BSL) are not only different, but actually mutually unintelligible shows that sign languages do not derive from spoken languages they are nested within.

Sign Language Acquisition

For most deaf children, the language acquisition process differs quite radically from how the

hearing typically acquire spoken language. A vast majority of deaf individuals (estimated to exceed 90 % – see, e.g., Mitchell and Karchmer 2004) are born into hearing families, which means that their relatives do not use a language that is sensorially accessible to them. Deaf children may, at some stage, start interpreting the movements of the lips, tongue, and face of their hearing family members as meaningful but the lipreading technique does not form a sufficient basis for natural language development. Such a limited input, combined with the fact that a deaf infant's hearing relatives do not usually learn any sign language, results in deaf children often showing delayed development of communicative skills.

Although it is very likely that, throughout the history of mankind, deaf people used various forms of gesturing (often referred to as homesigns, different from sign language in being inconsistent and generally lacking a systematic grammatical structure) as a tool of communicating with the hearing around them, it was only in the second half of the eighteenth century that complex sign languages started to evolve (Eriksson 1998). The ratio of profoundly deaf to hearing newborns is usually estimated to be 0.1 % (one in a thousand). Therefore, apart from very rare situations where an exceptionally high incidence of deafness resulted in the emergence of so-called village or shared sign languages (Nyst 2012), used by both deaf and hearing members of a given community (as in the case of the population of Martha's Vineyard – Groce 1985), most signers acquire sign language through peer-to-peer transmission in schools for the deaf. The first public school for the deaf was founded in the early 1760s by Charles-Michel de l'Épée in Paris, France. In the following decades, educational methods based on sign language started to spread around Europe and North America, which allowed for an unprecedented development of natural sign languages. However, in the second half of the nineteenth century many educators of the deaf adopted the so-called oralist approach, according to which sign languages should be rejected in favor of methods that focus on lipreading and speech training. Oralism

is now generally perceived by the deaf as a vivid example of discrimination (often dubbed as “audism,” i.e. a paternalizing attitude based on the assumption that hearing is central to human experience – Lane 1992).

How important a role deaf schools may play in the emergence of sign languages is manifested by a widely discussed example from Nicaragua. A sign language was born there in the 1970s when children that had been isolated in their families started to participate in a newly established school program. Although they were expected to learn spoken Spanish and lipreading, a signed communication system started to develop among them (with no adult influence), paving the way to what later became a creole-like sign language. Many linguists see this as an argument for the Chomskyan view that linguistic competence is rooted in an innate language faculty (Kegl et al. 1999).

Sign Language Communication

As first demonstrated by Stokoe (1960), sign languages are not based on mimetic gestures (pantomime). Each sign may be analyzed as a bundle of contrastive meaningless features – comparable to the phonemes of spoken languages. Individual words (signs) are composed into sentences in accordance with the rules of grammar. In principle, these basic mechanisms underlying signed communication are not in any significant way different from what happens in spoken languages. However, sign language syntax may be claimed to possess a unique characteristic: unlike the strictly linear syntax of spoken languages it allows for three-dimensionality. The signing space (i.e. the area in front of the signer's body) is exploited syntactically, semantically, and pragmatically in the visual-gestural communication (Perniss 2012). Particular locations in the signing space may be associated with discourse referents, resulting in a mapping of mental spaces onto the structure of a particular utterance. Spoken language words cannot be articulated at different spatial positions but sign language words can. This is

Sign Language, Fig. 1 The use of space in a sign language sentence

illustrated in Fig. 1 (extracted from a corpus of Polish Sign Language, PJM – Rutkowski et al. 2016). The signer is describing a lake surrounded by rocks. Each of the three snapshots of Fig. 1 captures a different location associated with a different rock. A spoken language equivalent of this sentence could include prepositions or other space-referring expressions. In sign languages, signers will typically convey this kind of information by modifying the place of articulation of a given sign.

The spatial aspect of grammar distinguishes natural sign languages from artificial manual codes that have been created around the world

with the aim of representing spoken languages visually (for instance, “Signed Exact English” or “Calqued Lithuanian”). Many hearing educators of the deaf prefer to use manually coded versions of spoken languages because they consider this strategy successful in bridging the gap between the deaf and the language of the hearing majority. However, mirroring the linear organization and the phraseological structure of a spoken language often results in an unnatural hybrid communication system that does not effectively fulfill communicative functions. Apart from lacking the spatial dimension, manually coded systems do not typically make use of nonmanual signals. Natural sign languages are articulated with the whole body of a signer. The hands play the most important role with respect to conveying the lexical basis of meaning but nonmanual signals (such as facial expressions, eye gaze, body leaning, head tilting, shoulder raising, mouthing, etc.) are used as, for instance, grammatical markers and their function is not merely ancillary. Because of their absence, deaf signers often perceive manually coded systems as difficult or even impossible to understand.

Conclusion

Being deaf does not equal being a sign language user. Many deaf children who are given a cochlear implant at an early stage of their lives and do not feel part of the signing community will never develop any fluency in sign language. However, those deaf individuals who use sign as their first and preferred means of communication should be considered members of linguistic minorities in their respective countries. As complex lexicogrammatical systems that allow the unlimited expression of thought, sign languages are full-fledged natural languages, their only unusual characteristic being that in most cases they are not passed on from generation to generation but rather through peer assembly (typically, in deaf schools and communities).

Definition

Communication occurs when one individual influences the behavior of at least one other individual through the information conveyed by its signals or cues. Whereas cues are often incidental byproducts of individual behavior or physiology that convey information, signals evolved specifically for the function of communicating (see ► [“Communication, Cues, and Signals”](#); Maynard Smith and Harper 2003). A signal is reliable when it is consistently and predictably associated with either the signaler's state or some salient aspect of the environment. In animal species, signals are generally reliable because of strong selection pressure on receivers to ignore or avoid unreliable signals or signalers – unreliable signals are therefore selected against.

Introduction

Communication is often a dyadic interaction between signalers, who produce signals, and receivers, who monitor signals. For decades leading up to the 1970s, the general view of animal communication was that individuals produce reliable signals to benefit both the signaler and the receiver. In his seminal book, *The Behavior of Communicating: an Ethological Approach*,

Smith (1977) developed the notion of communication as sharing of information between signaler and receiver, as a foundational mechanism of social regulation. “An event in which communication occurs through the agency of displays involves the behavior of at least two individuals, a communicator and one or more recipients, usually to their mutual advantage” (Smith 1977, pp. 10–11). Similar definitions of communication describing benefits to both signaler and receiver can be found widely in the ethological literature prior to Smith’s book.

A year after Smith’s book was published, Dawkins and Krebs (1978) argued against the notion of communication being the transfer of information for the general benefit of both signaler and receiver. Instead, they argued that communication is better understood as manipulation of the receiver by the signaler – communication occurs because signals and signaler behavior have evolved to benefit the signaler, often at the expense of the receiver. Under this view, signals are like propaganda, and they have evolved to persuade receivers to the signaler’s advantage. Dawkins and Krebs (1978) argued that deception, dishonesty, and exaggeration were the rule rather than the exception – signals should generally be unreliable so that receivers cannot easily predict signalers’ behavior. Signals are considered unreliable if they are not consistently correlated with either the signaler’s state or the environment.

Although the views advocated by Dawkins and Krebs influenced the field of animal communication for decades to come, research has clearly shown that signals are, by and large, reliable. Variation in signal structure or signal production is often reliably associated with aspects of the signaler or the environment that are important to the receiver and to the signaler. Given that signalers could benefit by manipulating receiver behavior with deceptive or otherwise unreliable signals, why do signalers so regularly produce reliable signals? One of the key reasons is that in many social species, signaler and receiver interests (those related to survival and reproduction) are often aligned with one another, such that both signalers and receivers benefit from honest communication.

Alignment of Signaler and Receiver Interests

Signals are generally correlated with conditions external to receivers and, as such, can provide crucial information to receivers that may cause receivers to alter their behavior. The more highly correlated a signal is to conditions external to receiver, the more reliable the signal is. In cases where interests of signalers and receivers align, a signaler may produce a signal to manipulate the behavior of a receiver, but both signaler and receiver will generally benefit from this communication (Bradbury and Vehrencamp 2011). Signaler and receiver interests are similar in many contexts involving kin selection, food calling, alarm calling (see ► [“Alarm Calls”](#)), mobbing behavior, social cohesion, or begging. As such, signals used in these contexts are generally reliable (Searcy and Nowicki 2005). For example, vervet monkey (*Chlorocebus pygerythrus*) signalers produce different types of alarm calls depending on whether they have detected a leopard, hawk, or snake predator. Upon hearing these signals, receivers will behave motorically in escape as if they had themselves detected the same predator (Seyfarth et al. 1980). Since each different alarm signal is produced exclusively when that predator is in the area, these signals are highly reliable. Individuals signal reliably in this species because of their aligned interests of gaining the fitness benefits that come from social living with the members of their group.

Another important example of reliable signals in the context of aligned interests comes from classic studies of Belding’s ground squirrels (*Spermophilus beldingi*; Sherman 1977). When terrestrial predators are detected, individuals often produce alarm calls, and these calls are costly – compared to a silent ground squirrel, a calling ground squirrel is twice as likely to be detected and attacked by the detected terrestrial predator. Of importance is the relatedness of individuals in the immediate environment of an alarm caller. Alarm callers are frequently reproductive females, and alarm calls are produced by them primarily when their own family members (such as siblings or offspring) are nearby. Despite

the increased costs of alarm calling to the signaler, reliable signaling can evolve through kin selection due to the high levels of relatedness of signaler and receivers in this system.

Prior to the point of parent-offspring conflict (Trivers 1974), the interests of parents and their offspring are clearly aligned with one another. In many altricial animals, young individuals produce “begging” signals when they are hungry. In tree swallows, *Tachycineta bicolor*, hungry nestlings produce begging calls at higher rates than sated nestlings, and playbacks of calls of hungry nestlings lead to more feedings of nestlings near those speakers than playbacks of calls of sated nestlings (Leonard and Horn 2001). Thus, the rate of calling by nestlings in this species, and perhaps other acoustic features of these signals, serves as an honest signal of need and influences parents’ feeding behavior accordingly.

Nonalignment of Signaler and Receiver Interests

In many instances, the interests of signalers and receivers only weakly align or are clearly opposed to one another. This can be observed frequently within certain types of mating system. For example, in mating systems where parental investment is unequal, individuals with higher parental investment (usually females) are typically the more discriminating sex. Individuals of the less discriminating sex (those with lower parental investment; usually males) signal to communicate their reproductive quality. In these mating systems, individuals of the less discriminating sex have the goal of as many matings as possible, to increase reproductive output. Individuals of the more discriminating sex, conversely, have the goal of achieving a quality mating to increase chances of having quality offspring. Therefore, signaler (usually males) and receiver (usually female) interests only weakly align, and we may expect to see dishonest signaling from signalers about their quality. An example of such deceptive signaling occurs in the Asian corn borer moth (*Ostrinia furnacalis*). In this species, moths react to predator bat echolocation signals by freezing.

Male Asian corn borers have evolved an ultrasonic vocal signal they use that also causes females to freeze, thereby increasing the males’ chances of mating with them for longer durations while bypassing the normal mate recognition and courtship sequence of the species (Nakano et al. 2013).

In aggressive conflicts between two individuals over access to a resource, interests of signalers and receivers are typically opposed. In these conflicts, where the goal for one individual is to defeat the other, we might expect to see cases of deceptive, or unreliable, signaling. In such cases, individuals may bluff signals related to their status, condition, quality, or fighting ability. In addition, unreliable signals can occur when an individual would benefit from avoiding an aggressive encounter it would be sure to lose. Such is the case in Augrabies flat lizards (*Platysaurus broadleyi*; Whiting et al. 2009). Some males appear phenotypically like females in terms of body coloration and can therefore better avoid aggressive interactions with territorial males and increase their own chances to reproduce with females attracted to the areas of those territorial males. In this species, the males that mimic females are able to do so visually, thus usually fooling the territorial males. However, they are not able to mimic chemical signals of females and therefore must avoid direct interactions with territorial males (Whiting et al. 2009).

Under the scenarios raised above with regard to nonalignment between signaler and receiver interests, we might expect substantial use of unreliable signals (Dawkins and Krebs 1978). Conversely, research shows dishonest signaling still seems the exception rather than the rule (Searcy and Nowicki 2005). Consider a situation in which a prey individual detects a predator that has detected it. The prey individual might be expected to produce signals that communicate to the predator greater condition, strength, or escape ability on the part of the prey individual than is true. If theory suggests we should see dishonest signaling in cases where signaler and receiver interests are not aligned, why do we typically see reliable signaling?

Why Are Signals Typically Reliable When Signaler and Receiver Interests Do Not Align?

There are several arguments (not necessarily mutually exclusive) for the reliability of signals even in cases where interests of signalers and receivers oppose one another. One straightforward example is the situation of signals that are sufficiently physically constrained that they cannot be faked – these are called index signals. Index signals are typically constrained by either the physical features of the individual producing the signal or by the experience of the signaler (Bradbury and Vehrencamp 2011). For example, male North American bison, *Bison bison*, produce loud and low frequency bellows in inter-male interactions over control of female harems, larger males produce lower frequency bellows than smaller males are able to produce, and lower frequency bellows are associated with greater male fitness (Wyman et al. 2012). Smaller males are not able to produce lower frequency bellows because of the smaller size of their vocal tracts in comparison to larger males, and vocal tract length constrains frequency (pitch) of sounds produced. In our own species, the frequency contours of phonemes (formant frequencies) and the spacing among those contours are strongly correlated with height and weight variation in both women and men (Pisanski et al. 2014). Given that variation in these frequency contours is thought to be derived from variation in human vocal tract length, and vocal tract length is related to body size, these correlations indicate that frequency contours of human phonemes may be index signals. With index signals, signalers have limited ability to choose which signals to produce and cannot bluff a better quality signal. Other common index signals include visual signals on the body of the signaler – in cases where the size of the signal communicates important information to receivers, larger signalers will often possess larger signals than smaller signalers simply by virtue of their differences in body size.

Conventional signals are signals that are typically energetically no-cost or low-cost to produce and are arbitrary in themselves but are

given meaning by the coding scheme used by signalers and receivers (Bradbury and Vehrencamp 2011). In situations where signalers have different interests than receivers and therefore we may expect cheating to occur, receivers react agonistically to signalers when their signals do not match the convention, thus increasing costs for cheaters (Guilford and Dawkins 1995). For example, banded wren, *Thryothorus pleurostictus*, males counter-sing in aggressive interactions with one another. Males have multiple songs in their song repertoires, and males share many songs. A male that counter-sings with the same song its opponent used is using the most aggressive strategy, and the opponent is likely to approach rapidly in escalation. A counter-singer using this aggressive strategy, if it is in relatively poor condition, is likely to be attacked by the opponent (Molles and Vehrencamp 2001). Thus, conventional signals are often reliable, even though they are physiologically inexpensive to produce, because of the costs of retaliation imposed by receivers.

Handicap signals are signals that are costly to produce and proportionally more costly for relatively low quality or poor condition signalers (Bradbury and Vehrencamp 2011; Zahavi 1975). Handicap signals are often tightly linked to the physical attribute about which they communicate. For example, male side-blotched lizards (*Uta stansburiana*) compress their bodies to produce a visual threat display in aggressive interactions with other males. These signals are handicaps because low-quality males cannot produce them as long as high-quality males, and experimental reductions in endurance (through treadmill running) result in decreased production of threat displays (Brandt 2003). Likewise, increased production of threat displays results in decreases in endurance. While the original hypothesis referred to physical, or receiver-independent, costs of signals that are different for low- and high-quality individuals (Zahavi 1975), recent theory points to the importance of social costs even with energetically costly signals (Számadó 2011). Social costs and physiological costs of signaling are not mutually exclusive and may occur together in a system (Tibbetts 2014).

Proximity signals are those given in contexts where signalers interact closely with their opponents. The use of song matching in song sparrows (*Melospiza melodia*) is an example of a proximity signal that predicts the probability of a bird attacking in territorial disputes. Using a model bird and a sophisticated playback technique, researchers demonstrated that these sparrows use type-matching (producing songs that match the type of songs produced by an intruder bird) to reliably indicate their eventual attack on a simulated intruder bird in territory defense. Birds who initially type-matched simulated intruding bird but quickly switched song types as the intruder approached were much less likely to attack the invading mount (Akçay et al. 2013). This signal has costs – previous research has shown receivers are more likely to react aggressively when their songs have been type-matched (Burt et al. 2001), so individuals who type-match in close proximity to the intruder must be prepared for the dispute to escalate. Again, signalers have some degree of choice when making proximity signals but must pay for cheating through additional costs or loss of benefits compared to signalers who signal honestly (Bradbury and Vehrencamp 2011).

Human interactions in social groups are subject to similar pressures to ensure reliability. Displays of wealth, skill, or productivity are signals that represent social capital, which, in many cultures, is essential to secure marriage proposals and alliances. For example, making conspicuous purchases and wearing jewelry signals the stature and wealth of the signaler, particularly for newly wealthy individuals who do not yet have a high reputation (Bird and Smith 2005). These signals are also known as “symbolic capital” and can take the form of displays of favor and generosity. If the cost of the resources shared in such displays is less than the value of the social capital gained by the display, the display is a conventional reliable signal of an individual’s skill in generating resources. Both signalers and receivers benefit from gaining marriages and alliances from those with higher status than themselves, so dishonest signals could be expected. However, the cost to generate the resources required for these displays is prohibitive and limits the ability of a signaler

to bluff. Particularly in cultures where wealth displays are connected to marriages and other interfamily alliances, receivers have ongoing expectations for those that signal wealth such that dishonest displays would be too costly to consistently perform. When signalers cannot meet receivers’ expectations, they incur social and resource costs if they attempt to signal their wealth dishonestly (Bird and Smith 2005).

One last issue to consider for addressing widespread signal reliability is the general principle of strong selection pressure on receivers to avoid being influenced or deceived by unreliable signals (Krebs and Dawkins 1984). If signalers were to constantly cheat when signaling, the communication system between receivers and signalers would break down, since there would be no incentive for receivers to pay attention to signals produced by others if those signals cannot be trusted. Selection pressure on receivers to discriminate more effectively reliable signals from unreliable signals should generate populations of better discriminators. This, in turn, will serve as a strong selection against unreliable signalers.

When Is Deception Expected?

Signalers are generally not able to fake an index signal, meaning that index signals remain reliable because deception is not possible. However, for non-index signals, if a signaler is able to bluff or produce a dishonest signal, they may be expected to do so when the benefits of producing a dishonest signal outweigh the costs. For some conventional, proximity, or handicap signals, costs for producing a dishonest signal may be enforced socially. These socially induced costs are also known as “potential costs,” since the receiver must (1) be aware of the dishonesty and (2) choose to punish the signaler for their dishonesty, otherwise the signaler is rewarded for cheating (Számádó 2011; Webster et al. 2018). Such unreliable or dishonest signals must be rare in the population to persist, however, if selection on receiver discrimination is strong, as mentioned above.

We may also expect dishonest signaling in cases where receivers incur higher costs for ignoring a reliable signal (false negative) than for responding to a dishonest signal (false positive). Forked-tailed drongos (*Dicrurus adsimilis*), for example, forage in mixed-species flocks where other species respond to alarm calls produced by drongos by displaying antipredator behavior. However, drongos sometimes dishonestly produce alarm calls, scaring other species away from food resources that drongos then steal (Flower 2011). Drongos also flexibly use a variety of alarm calls to avoid others detecting their dishonesty (Flower et al. 2014). This dishonesty persists in the signaling system because receivers incur larger costs for ignoring honest alarm calls (they are more likely to be killed by a predator) than they do for responding to dishonest ones (they are more likely to lose a foraging opportunity).

One interesting case of common deception that does not seem to involve the relative false positive and false negative costs mentioned above is that of regenerated claws in male fiddler crabs (*Uca* species; Wilson and Angilletta 2015). Regenerated claws are typically weaker than the original claws, and males with regenerated claws are therefore at a disadvantage if they get into actual fights with other males. Although the regenerated claws in some species look different from original claws, evidence suggests that neither male opponents nor potential female mates can discriminate the two claw types at the typical distances these crabs wave their claws when communicating. It is possible that selection pressure on at least female receivers is not strong enough to select against this unreliable signal, as males with regenerated claws do not sire young at any disadvantage in comparison to males with original claws.

Conclusion

In situations where interests of signalers and receivers are strongly aligned, reliability of signaling systems typically occurs due to those shared interests. In situations where interests of signalers and receivers diverge, reliability of the

signaling system typically occurs due to the fact that receivers have their own interests, and with selection for stronger discrimination ability over generations, populations of receivers will no longer pay attention to a signal if it is routinely dishonest (Laidre and Johnstone 2013). This puts pressure on signalers to signal in a way that can be validated by receivers, and to maintain a reliable signaling system (Laidre and Johnstone 2013), even if they are able to cheat occasionally. For a signal system to be reliable, the signal in question does not need to be honest 100% of the time. Instead, honest signals are “honest on average,” meaning they are reliable enough that receiver benefits more from attending to them than from ignoring them (Laidre and Johnstone 2013). Indeed, the fact that signals are honest on average is what makes deceptive signaling possible, provided it is relatively rare in the population – “reliability is necessary if receivers are ever to respond to a signal at all” (Searcy and Nowicki 2005, p. 224).

Cues to weight; Signaling body dimensions

Definition

The perception of cues related to visual and acoustic body size provides socially relevant information linked to an individual's fitness.

Introduction

The body size of individuals varies and is associated with sexual maturity, health, dominance, strength, and overall genetic quality. Physical size is a crucial determinant of various socially relevant characteristics of an individual across many species. The perception of conspecifics' body size is thus involved in various social contexts including physical confrontations.

The main components of body size are body weight, height, and muscularity. These factors have been shown to be linked to success in physical confrontations. Potential competitors can thus base their fight-or-flight decisions on body size assessments (Sell et al. 2010).

Body size-related cues can be perceived by several modalities. Multimodal perception can provide overlapping information and thus reduce the risk of inaccurate assessment. Alternatively, each modality can provide additional information, thereby helping to increase the accuracy of judgement. Acoustic and visual assessment of others prior to close contact is common in many species, since it helps to reduce the risk inherent in direct

physical contact. Since the accuracy of assessment of physical characteristics solely from visual cues may suffer due to obstacles in the environment, excessive distance, and/or low luminance, acoustic cues can supplement or replace solely visual information.

In humans, assessments of others are initially guided primarily by visual and acoustic cues. Our physical appearance and voices are socially rich stimuli which attract attention and offer plenty of cues to socially relevant qualities.

Acoustic Cues to Body Size

Apart from conveying linguistic information, human voice carries cues to various physical, social, and fitness-related characteristics of speakers such as age, sex, and body size (Pisanski et al. 2014).

Fundamental frequency (F0) and formant frequencies (FF) are the two most studied features of the human voice. According to source-filter model of speech production, which is based on the basic idea that voice/sound is produced by expelling air from the lungs (the source) through vocal folds, vocal tract, and the mouth (the filter) where it is modulated into speech. F0 and FF are anatomically and functionally independent (Fant 1960). Fundamental frequency is determined mainly by the length and the mass of vocal folds, which vibrate during phonation-modulating flow of air expelled from the lungs. Produced sounds are then perceived as having a certain pitch. Increase in the folds' thickness results in a lower F0 and a lower perceived voice pitch.

Formant frequencies (FF), on the other hand, i.e., the spectral characteristics of speaker's voice perceived as the voice timbre, are determined mainly by speaker's supra-laryngeal voice tract length (VTL) and its resonance. Formants are more anatomically constrained than F0 by the length and dimensions of the vocal tract, which is related to skull size and body height (Fitch 2000).

F0 and FF are associated with individuals' stable characteristics due to the exposure to testosterone during development and are

consequently anatomically related to physical size (Rendall et al. 2005). In boys, elevated levels of circulating testosterone during puberty lead to a lengthening and permanent thickening of vocal folds, which result in a lower F0 (Jenkins 1998). Further, the descent of larynx results in a lowering of formants and narrowing of formant dispersion (formants being produced closer together). The acoustic effect of these changes is that the voices of adult men are lower-pitched and deeper or, in other words, more resonant and rather monotonous than the voices of women or prepubescent children. Longer vocal tract and thicker vocal folds thus produce lower FFs and lower F0, which can thus serve as potential cues to a bigger body size.

Research which tested the role of F0 and FF as indicators of size has generally confirmed that both independently predict variation in body size among different species (Pisanski et al. 2014; Rendall et al. 2005), meta-analyses of acoustic predictors of human voice showed only weak or marginally negative relationships between both F0 (accounting for less than 2% of the variance) and FF (accounting for up to 10% of the variance) and the height or weight within each sex (Pisanski et al. 2014).

Listeners demonstrate sensitivity to variations in F0 and FF and a high consistency in associating lower F0 and FFs with larger speakers. Their judgments, however, tend to be incorrect with respect to speakers' actual size (Pisanski et al. 2014). This relatively low accuracy in assessing body size from voice might be due to the presence of other characteristics unrelated to height or weight, which, too, affect the quality of human voice.

Current research indicates that men with a lower voice pitch are significantly stronger than those with high-pitched voices, and that raters are able to estimate strength from vocal cues accurately and independently of their height or weight assessments (Sell et al. 2010). Some studies which investigated the relationship between voice acoustics and muscularity suggest a negative correlation between F0 and men's shoulder-to-hip ratio (i.e., lower FF indicates individuals with larger upper body musculature). Other

studies, however, did not confirm this association (Pisanski et al. 2016).

Human voice also provides cues to speaker's current state. Certain psychological states, such as self-confidence, fear, or rage, can modulate the position of the larynx and change the tension of the vocal folds, thereby affecting also the resulting F0. The F0 can be modulated to deceive others and to disguise or exaggerate the characteristics of an individual (Fitch 2000). This feature is not unique to humans. It has been suggested that its original selective advantage may have been in enabling individuals to simulate the vocalizations of larger conspecifics, thus exaggerating their own size, and reducing the degree to which FF accurately indicate body mass and shape (Pisanski et al. 2016).

Most recently, scholars have been focusing on some less variable voice parameters, such as non-mean-based F0 measures (measuring voice pitch deviation from its baseline), voice jitter (frequency perturbation), shimmer (amplitude perturbation), and harmonic-to-noise ratio (which is related to the mass and oscillating properties of the vocal folds). These characteristics are supposed to be sexually dimorphic, related to body size and shape via shared influence of sex hormones on these vocal properties, and linked to the development and distribution of lipid and muscle mass (Pisanski et al. 2016).

Visual Cues to the Body Size

In many species, direct visual inspection of the physical size of others is the primary determinant of social dominance. It is therefore not surprising that individuals try to appear physically larger to make a more intimidating impression. Interestingly, direct observations of overall body size of others and the effect of nonverbal behavior on the perception of body size have not yet been thoroughly tested in humans. Available evidence suggests that changes in apparent physical size (e.g., elevation by standing on a platform) affect the perceived height of the individual in question (Schwartz et al. 1982). Perceived body height can also be manipulated by altering other

perceptual cues to size, such as the size of background features, which then increase or decrease the apparent size of individuals (Marsh et al. 2009). Moreover, nonverbal cues such as expansive body posture or posture openness can also make the displayer appear physically larger in eyes of others (Marsh et al. 2009).

Based on facial traits, we spontaneously attribute various personality characteristics. High levels of testosterone are thought to be an important determinant of both the body size and changes to the shape of face during puberty, because testosterone has a strong anabolic effect on the musculoskeletal system, thus influencing various features including the volume of lean body mass and differences in muscle strength. Through the mechanism of hormone action, facial morphology thus seems to be connected to both muscularity and overall body size.

Several studies have investigated a relation between testosterone levels and facial appearance. Their aim was to identify visual cues used to estimate height and weight from the face. Generally, taller people are reported to have more elongated faces than shorter ones (Windhager et al. 2011). Facial elongation (full length of the face divided by its width) increases from infancy to adulthood as the lower jaw develops and starts protruding, making the face less round and more oval. Heavier men and women have wider and more square faces, and heavier men have also rounder lower facial regions (Coetzee et al. 2010). These facial shape cues can be quantified by width-to-height ratio, perimeter-to-area ratio, or cheek-to-jaw-width ratio (for a review see Coetzee et al. 2010). Adiposity produces a typical facial shape because large percentage of facial fat is allocated to the cheek area, buccal fat pads, thus providing a visual cue to body size (Coetzee et al. 2009).

Available evidence indicates that people use the abovementioned or related facial cues to assess body weight and height of others, and they are fairly accurate in their judgments. Individuals with wider, squarer faces, and rounder lower faces are correctly judged to be heavier (Coetzee et al. 2010), while people with longer faces are judged as being taller (Re et al. 2013).

We should, however, bear in mind that visual cues in 2D images (portrait photographs) are fairly limited, especially for volumetric weight estimates (Coetzee et al. 2010). Moreover, we do not usually view faces from the perspective of a typical facial stimuli presentation, i.e., a vantage point centered on and aligned with their faces. Humans show relatively significant height dimorphism and since men are typically higher, they view women's faces from slightly above, while women tend to view men's faces from slightly below (Burke and Sulikowski 2010). When this vantage point is manipulated, participants tend to overestimate body weight for faces presented from a lower vantage point and underestimate it for faces presented from a higher vantage point (Schneider et al. 2012).

Conclusion

Assessment of body size is an important part of first impression formation. It is involved in various social interactions including physical confrontation. Most previous research on perception of body size focused on vocal and facial cues. It has been shown that the main vocal parameters affecting the perception of body size are fundamental frequency and formant frequencies. However, attribution of body size based on these vocal cues tends to be inaccurate. On the other hand, people are usually relatively accurate when judging body height and weight from facial images. The main facial cue related to body weight is a rounder lower facial region, while body height is associated with elongation of the face. Interestingly, relatively little is known about behavioral cues to body size. Further, to our best knowledge, no studies have as yet tested cross-modal integration of individual body size-related cues.

Significance of Helping

Yana Lakman

Brock University, St. Catharines, ON, Canada

Synonyms

Altruism; Caregiving; Cooperation; Prosocial behavior

Definition

Helping is assisting, supporting, or being of benefit to someone (Merriam-Webster definition)

Introduction

What Is Helping?

The Merriam-Webster dictionary defines “helping” as assisting, supporting, or being of benefit to someone. However, other terms can signify helping: altruism, prosocial behavior, cooperation, and caregiving. Nowak (2006) defines a cooperator as someone who benefits others at a cost to themselves. Helping and cooperating can both be seen as prosocial behaviors (Pettygrove et al. 2013; Warneken and Tomasello 2007). In some instances, helping may develop first, before

cooperation (Warneken and Tomasello 2007). Sommerville et al. (2013) found that there are two related helping behaviors that comprise prosocial tendencies: instrumental and informational help. Instrumental help includes providing help in response to something that has happened (e.g., when a helper brings back an item that another person has dropped). Informational help includes providing help by information (e.g., when a helper tells a person where something is if he or she doesn't see it).

Overall, previous studies that explored this topic have suggested that helping begins early in life (Pettygrove et al. 2013; Sommerville et al. 2013; Warneken and Tomasello 2007). It has been found that children are very eager to help adults (Sommerville et al. 2013). Sommerville et al. (2013) found that in most cases, they help adults instrumentally, which means that often-times, it is not even requested. However, research found that they also tend to assist same-aged peers by either helping to reach for a toy or by retrieving it for them even when it was not requested (Hepach et al. 2017). But why would they do it is a whole other issue.

Why Do We Help?

Historically, helping others would have required two main elements: (1) a person's relatedness to the other (i.e., kin selection; Hamilton 1964) and (2) the act of returning a favor (i.e., tit for tat or reciprocal altruism; Trivers 1971). Helping behavior was mostly targeted at a kin due to genetic resemblance (Dawkins 1989; Hamilton 1964). This was also known as family-based altruism (Dawkins 1989; Hamilton 1964). However, in most human-built societies, kin-like altruism had expanded beyond familial genetic resemblance and into communities that were made up of strangers who lived in close proximity to one another (Bowles and Gintis 2004). By creating cooperative communities, who shared food and info, survival was enhanced (Bowles and Gintis 2004). Thus, helping behavior toward "the sick, the wounded, the very young and old" (Trivers 1971, p. 45) offered opportunities for reciprocal altruism and promoted survival. However, reciprocal help was not always a requirement; some

helping behaviors were instrumental, in that they occurred toward other people who were unrelated or unknown to the helper or without any benefit in return (Warneken and Tomasello 2006). This may be because of group affiliations (Over and Carpenter 2009). Over and Carpenter (2009) studied infant's likelihood of helping when primed for affiliation. Results revealed that infants that were primed with affiliation helped the researcher more than when they were primed with individuality. In the latter case, helping behaviors actually decreased (Over and Carpenter 2009).

de Waal (2008) summarized what drives directed altruism (i.e., helping others who were unrelated to the helper). The author provides three scenarios that would motivate one's altruism. One may experience altruistic impulse. This is when one may help someone who is asking for it or is in visible distress. He or she may also experience learned altruism. This is when one may help someone because their helping behavior has been reinforced in the past. Finally, one may experience intentional altruism. This is when one may help someone because they think this action will be repaid for in the future. This could also occur when one may help just for the sake of helping.

From an evolutionary perspective, such altruism should not have been favored because it comes with costs and may reduce one's own fitness (Dawkins 1989). Dawkins' (1989) example of a bird calling for food or for warning illustrates an altruistic behavior; the bird is trying to let others in the flock know that there is food or a predator nearby. The potential cost could be intriguing the interest of the nearby predator and potentially dying. Hence, helping or cooperating does not make sense evolutionary, especially if there are limited opportunities to ensure one's own genetic survival (Dawkins 1989). It is so puzzling that Nowak (2006) states at the end of the article that "natural cooperation" should be a "third fundamental principle of evolution beside mutation and natural selection" (p. 1563). On the other hand, altruistic actions may be adaptive in an indirect way. Ligon and Stacey (1989) showed that in some situations, cooperative breeders, who feed and help non-related offspring, indirectly increase their own personal fitness by building

their personal and social relationships with the other birds. This may then increase their breeding status and ease of emigration to other spots (Ligon and Stacey 1989).

The reason or motivation behind helping behavior may include two mechanisms. First, de Waal (2008) summarizes evidence that suggests that this behavior was indeed evolutionary “selected” but runs via another mechanism of empathy. The author argues that the capacity for empathy started to evolve in parents and offspring dyads and quickly transferred to others who were living in close proximity and were a part of one’s social circle (de Waal 2008). Paciello et al. (2013) showed that even in situations when costs to the helper were high, the role of empathy still prevailed; high empathy yielded helping behavior (an altruistic response). Second, familiarity may be key; if children were familiar with the person requiring help, they were more likely to help him/her (Allen et al. 2018; Wynn et al. 2017). Thus, some evidence suggests that perhaps helping non-related beings is still beneficial.

Who Is More Likely to Help?

Helping behavior is not unique to humans. Both human infants and chimpanzees have the ability to help another person, but as one would expect, chimpanzee’s helping behavior was more limited (Warneken and Tomasello 2006). Interestingly, several studies showed that helping behaviors develop during earlier years of life, in particular around the second year or younger (Pettygrove et al. 2013; Sommerville et al. 2013; Warneken and Tomasello 2007). This suggests that younger children have the capability of helping others. While it has been shown that younger children have helping tendencies, older children (those who were 30 months old) still help more readily (Svetlova et al. 2010). This suggests that helping, although present in young children (as young as 2), may very well increase with age.

One study that explored sociability in helping found that children who were more approachable to the researcher helped more often (Hammond and Carpendale 2015). This could suggest a certain personality dimension that contributes to one’s helping tendencies. However, environmental

factors may also play a role in who is more likely to help. Hepach et al. (2017) found that children who grew up with siblings helped more while those who attended kindergarten helped less. Another research, by Hammond and Carpendale (2015), which examined parental scaffolding, found that mother’s scaffolding increased children’s helping behaviors.

Furthermore, it could be argued that culture shapes helping behavior. For instance, helping, in a caregiving literature, is a female-biased behavior. From an evolutionary perspective, this makes sense as the parental investment theory explains why women are usually more responsible for increased caregiving behaviors (Dawkins 1989; Geary 1998). Other studies also found that females are more empathetic (Ashton et al. 1998; Davis 1983), more altruistic (Ashton and Lee 2007), and better at perspective taking (Batson et al. 2007). This may explain why females provide the bulk of care. However, these are relative, not absolute differences, heavily influenced by cultural norms and ideals (e.g., Barry et al. 1976; West and Zimmerman 1987). For instance, in Hunter-gatherer societies, such as the Baka, males participate in care for their siblings perhaps even more than females (Hirasawa 2005), which, due to its’ paternal investment, ensures offspring survival (Geary 1998). Today, males play a significantly greater role in caregiving. This may be due to the contemporary shift that views males and females more similarly (Fine 2017).

Conclusion

The Significance of Helping

To conclude, Warneken (2015) suggests that it would be possible to highlight the significance of helping by reviewing why this behavior was favored to begin with. Helping the kin or even a group of strangers may be favored because it ensures survival of one’s genes. Furthermore, helping maintains the cohesion of a community and enhances the morality of humanity. Can we imagine a society or a family unit that is characterized by lack of helping, cooperating, or caregiving? The answer is no.

Nowadays, helping behavior is more culturally and developmentally reinforced. For these reasons, some youngsters' helping behavior is not easily accepted. For instance, young carers, children and youth who help ill, disabled, or addicted family members, are less likely to get recognition for their role as helpers (Charles et al. 2009). However, since they help significantly to ensure survival of their family unit, their helping behaviors are indeed adaptive and should be recognized as such (Lakman et al. [under review](#)).

Silver Fox Domestication Experiment

Lee Dugatkin

University of Louisville, Louisville, KY, USA

Synonyms

Artificial selection; Domestication; Evolution

Definition

An ongoing, six-decade-long experiment on the domestication of silver foxes in real time.

Beginning in 1959 and continuing to this day, a team of Russian geneticists, led by Lyudmila Trut, has been running one of the most important biology experiments of the twentieth, and now twenty-first, century. The experiment was conceived by Trut's mentor, Dmitry Belyaev, who initiated an experiment to study the process of domestication in real time. Belyaev was especially interested in understanding the domestication of wolves to dogs, but rather than using wolves, he used silver foxes (*Vulpes vulpes*) as his subjects.

As a result of his reading of Darwin's *The Variation of Animals and Plants Under Domestication* (Darwin 1868) and his own interactions with domesticated animals, Belyaev was aware that domesticated species tend to share a suite of characteristics that include floppy ears, short/curly tails, juvenilized facial and body features, reduced stress hormone levels, mottled fur, and relatively long reproductive seasons. That suite of traits has been dubbed the domestication syndrome, and one of Belyaev's interests was why the domestication syndrome exists. We have domesticated species for many reasons, including transportation, food, companionship, and protection; but no matter what domesticated species are selected for, over time, they begin to display traits in the domestication syndrome. Why?

Belyaev hypothesized that the early stages of *all* animal domestication events involved choosing the calmest, most prosocial-toward-human

animals – the tamest animals – and that all of the traits in the domestication syndrome were somehow, though he didn't know how, genetically linked to genes associated with tameness. He and Trut put those ideas to the test (Trut 1999; Trut et al. 2009; Dugatkin and Trut 2017). They and their team developed a scale for scoring tameness. How a fox scored on this scale was the *sole* criteria for selecting foxes to parent the next generation. Every generation they tested hundreds of foxes, and the tamest 10% were selected to parent the next generation.

Starting with almost wild foxes, within six generations, selection based on tame behavior alone produced a subset of foxes that licked the hand of experimenters, could be picked up and petted, whined when humans departed, and wagged their tails when humans approached. In the earliest years of the experiment, the tamest of the foxes made up a very small proportion of the animals in the experiment; today they make up more than 75% of the experimental population.

Selection for tameness also resulted in the emergence of traits in the domestication syndrome. With a decade, some of the domesticated foxes had floppy ears and curly tails. By generation fifteen of the experiment, domesticated foxes had stress hormone levels about half that of wild foxes. Over the course of the experiment, domesticated foxes began to display mottled fur patterns, more juvenilized facial and body shapes, and longer reproductive periods. Social cognition experiments have also found that the domesticated foxes are as good as dogs at following at human gaze.

When Belyaev first hypothesized that selection for tameness would lead to the emergence of traits in the domestication syndrome, he did not have a proposed mechanism. The neural crest cell hypothesis, first proposed in 2014, may provide that mechanism (Wilkins et al. 2014). Very early on in animal development, neural crest cells migrate from the neural crest to glands in the endocrine system, bone, fur, cartilage, brain, and other spots in a developing embryo. The neural crest cell hypothesis proposes that selection for tame behavior reduces the number of migrating neural crest cells, which in turn leads to changes

in fur coloration, facial structure, the strength of cartilage (affecting floppy ears, curly tails, and so on), hormone levels, the length of the reproductive season, and more.

The silver fox domestication experiment is now entering its 60th year at its home at the Institute of Cytology and Genetics in Novosibirsk, Russia. Trut turned 85 years old in 2018 and remains the lead investigator on the work to this day. Belyaev died in 1985.

Simon Baron-Cohen (Darwinian Psychiatry)

Jeffrey Niehaus

Christopher Newport University, Newport News,
VA, USA

Definition

Dr. Simon Baron-Cohen is a developmental psychopathologist and cognitive neuroscientist, most known for his work with autism. He was born on August 15, 1958, and graduated with his Ph.D. from University College London under the direction of Dr. Uta Frith. He currently works as a Professor of Developmental Psychopathology at the University of Cambridge and is also a Fellow at Trinity College, Cambridge.

Introduction

Dr. Baron-Cohen has made several distinct contributions to the understanding of autism over the course of his career. He articulated the cognitive model associated with “mindblindness” and has more recently proposed the idea that autism is a form of “extreme male brain” associated with male fetal sex hormones and a tendency for “systemizing” (as opposed to empathizing). In addition, he has pioneered unique instruments in the assessment of abilities relevant to autism, including the autism-spectrum quotient (or “AQ”), and an assessment of one’s ability to read emotional states from eyes.

Proposed Cognitive Model from “Mindblindness”

In his 1995 essay “Mindblindness,” Baron-Cohen discusses the idea that autism stems from the inability to perceive social information. This is analogous to the way in which colorblind people have the inability to perceive different wavelengths of light. After introducing this idea, Baron-Cohen proposed a specific array of cognitive modules that allow for mindreading in neurotypical individuals. These are: the Intentionality Detector (ID), the Eye-Direction Detector (EDD), Shared-Attention Mechanism (SAM), and the Theory of Mind Module (ToMM). The model proposed by Baron-Cohen is closely related to the model proposed by Alan Leslie (1994). They cover much of the same ground, but differ in which modules are responsible for which functions.

In Baron-Cohen’s model, the ID is tasked with identifying those objects that, by virtue of their motion, are candidates for having mental states. An animate object will move in a way that is special, at least compared to inanimate objects. An animate will have self-propelled motion: it will ACT, as opposed to simply being acted upon. Also, its motion will have meaningful direction and, therefore, be possible to describe with intentions. An object that moves towards another object or moves away from another object is an animate that the ID mechanism may interpret as having a goal: to approach an object of desire, or to avoid a harmful object. The ID mechanism is proposed to be functional quite early in life, as demonstrated by multiple studies in which infants seem able to interpret behavior as goal-directed based solely on the motion patterns of geometric shapes (Gergely et al. 1995; Hamlin et al. 2007). Importantly, the Intentionality Detector mechanism is proposed to be multimodal, so that animate motion can be detected through sight, touch, or sound.

The Eye Direction Detector

In contrast, the EDD is proposed to be a part of the visual system and sensitive only to eye-like stimuli. The mechanism can be described as having three related functions: the detection of eye stimuli in the

first place, the calculation of the direction of the gaze of those eyes, and the inference that the owner of those eyes is aware of the existence of whatever the eyes are looking at (that is, an agent “sees” the thing towards which the eyes are oriented.)

The Shared Attention Mechanism

Once a brain is capable of identifying agents (ID) and appreciating the things of which the agent is aware (EDD), the output of these functions can be combined into what Baron-Cohen calls “triadic representations.” This is an appreciation of the fact that I, and another agent, can potentially both direct our attention to the same third thing. In this way, importantly, we are able to share information with each other regarding another person or object. Such joint attention is a paramount skill in the transfer of relevant information about the world, and most very young children seem quite keen to establish joint attention. Goals (inferred by the ID) and eye direction (inferred by the EDD) are synthesized by the SAM in order to determine that a person may *want* the thing that they are looking at. (It should be noted that the role of eyes, so central to the functioning of EDD, can be played by other relevant input. Children who live their entire lives without sight nevertheless seem able to develop the inputs that allow SAM To function normally.) However, the SAM is limited in that it can only function when the third object can be confirmed to be present and being perceived, in the moment, by both parties. In order to share information and contemplate things that are not currently being observed, another module is necessary.

The Theory of Mind Mechanism

The Theory of Mind Mechanism is responsible for inferring the “epistemic mental states,” which include things like knowing, believing, deceiving, and wondering. These states capture what is going on inside an organism’s head and are very closely related to what an organism is likely to do. This allows for the representation of things that are not currently present (such as, “John remembers that his car is parked in the Itchy Lot.”) Of course, none of these epistemic mental states can be observed

directly, even with the most modern of neuroimaging techniques. They must all be inferred from the clues present in the environment, such as eye gaze. (That is, if a person appears to be looking longingly at a new bicycle, it can be inferred that the person desires the bicycle and may be willing to engage in a series of actions with the goal of getting it. As such, this person may be willing to contribute to your welfare if you are able to contribute to their goal of owning the bike.) In that sense, the Theory of Mind Mechanism is about a theory, since epistemic states are merely theorized or inferred. We never have direct evidence of their existence. In fact, Baron-Cohen does not commit himself to the actual and literal existence of things like beliefs and desires and is content with the possibility that these things are merely hallucinated in order to help summarize information in a way that helps us to make sense of behavior.

The ID and EDD mechanisms are proposed to feed information to the SAM module, and the outputs of the SAM module are proposed to spur the development of the ToMM module. Thus, an interruption in the development of any one of these could result in a person who is not able to represent epistemic mental states or use them in a predictive “theory-like” way. In Baron-Cohen’s view, this is very much the essence of what it is to be a person with autism.

The Autism Connection

Research into the specific abilities and disabilities of people with autism have revealed a remarkable set of intact abilities, coupled with specific deficits. Autism is not characterized by a general lack of intelligence but by the impairment of functions that seem to interfere with communication and social appropriateness. Baron-Cohen’s own work has suggested that children with autism are quite able to infer an agent’s goals, follow the gaze of their eyes, and even know that the agent will be sad or happy depending on whether or not they get what they want. For these reasons, it is unlikely that autism is characterized by an impairment of either ID or EDD. On the other hand, evidence leads to the conclusion that there are large problems with the SAM, in that children with autism do not

typically attempt to draw others' attention to interesting objects, nor do they seem particularly interested in monitoring the gaze of other people.

Furthermore, the majority of children with autism seem to be impaired in representing epistemic mental states. This prevents them from efficiently dealing with information about what other people know or believe. Autistic children tend to fail the classic False Belief Task, in which one character sees an object being placed at location A but is then unaware of the object's removal to location B. While the neurotypical child will appreciate that the character will look in location A for the object (because she *thinks* the object is in location A), a child with autism will persistently guess that the character will look in location B (where the object actually is). This pattern of response among people with autism makes sense, as a prediction of action towards location A hinges on the representation of the character's epistemic mental state "thinks that the object is in location A".

Eyes and Emotions

Baron-Cohen also describes children with autism as deficient in their ability to infer emotional states from facial expressions. While it may be possible to predict emotions from *circumstances* ("Tommy lost his truck. Now Tommy is sad."), it is something else to be able to infer that Tommy is sad because his mouth is turned down and his eyes are red and squinting. In his work, Baron-Cohen created stimuli in which the only facial features available to express emotions were the eyes, and found that neurotypical males show a deficit in performance relative to females, that is an echo of the deficits in autism. That is, while the average male is a little bit worse than the average female when it comes to reading emotions from a snapshot of eyes, a person with autism is far worse (Fig. 1).

This pattern of "neurotypical male is slightly bad at something on which a person with autism is

An example of a (male) stimulus used: in the first version word choices were serious (correct) vs. playful. In the revised version the word choices were serious (correct), ashamed, alarmed, and bewildered.

A second (female) example from the Eyes Test: in the first version the word choice was reflective (correct) vs. unreflective. In the revised version the word choice was reflective (correct), aghast, irritated, and impatient.

Simon Baron-Cohen (Darwinian Psychiatry), Fig. 1 Examples of the revised Reading the Mind in the Eyes test, from Baron-Cohen et al. (2001b)

quite bad” presents itself repeatedly in the “extreme male brain” theory of autism.

Autism and “Extreme Male Brain”

The extreme male brain theory of autism (Baron-Cohen 2002) is predicated on the measurement of two variables, each of which show significant amounts of individual differences. The first of these is “empathizing,” which is not a new concept. A person high on empathizing will be adept at understanding the emotions, motivations, intentions, and thoughts of others. They will be able to quickly and easily communicate with other people and navigate the social world fluidly. On the other hand, the dimension of “systemizing” involves the attempt to understand physical systems with inputs and outputs in terms of how their parts interact. For instance, if a person were approaching a bicycle with a systemizing approach, they might observe that the chain travels around in a loop when the bicycle is moving. This correlation between the motion of the bike and chain might lead to the further understanding that the chain is transferring power from the pedals to the rear wheel.

While the understanding and prediction of people is *also* the understanding and prediction of a physical system, the system in question is so perversely complex that it calls for a specialized brain mechanism to do the job easily and automatically. In other words, it might be theoretically possible to understand all of the physical inputs, outputs, and processes that go into something like figuring out when you should and shouldn’t tell a dirty joke. However, if we attempted to apply what Daniel Dennett calls the “physical stance” to this problem, it would be too cumbersome to solve. However, through a series of automated shortcuts and assumptions, we can intuitively get the right answer by using what Dennett calls the “intentional stance”: treating a person-object like a special kind of thing that is driven by somewhat mysterious emotional states, desires, and knowledge.

A person high on systemizing may be very, very skilled at understanding the individual parts of an interactive system, but this will not get them

very far at all when trying to deal with the complexity of human behavior.

Unsurprisingly, females are typically found to be higher on empathizing than males. Evidence of this comes from the typically superior female ability to do things like read emotions from faces, take turns, value and display empathy, value relationships, communicate with language, and refrain from violence and aggression. Males, on the other hand, typically excel at tasks that require the scrutinizing of parts, such as: math, physics, engineering, construction, and map reading. They tend to gravitate towards toys and adult occupations that stress these abilities. Males also tend to perform better on specific cognitive tasks that require isolating the perception of a certain part of a system, such as the mental rotation task, Rod and Frame test, and Water-Level task.

It is yet to be determined how much of this difference is due to stable differences between males and females and how much is due to expectations from others. Almost certainly, these two factors resonate and reinforce each other. However, research has established a link between increased levels of fetal testosterone and a reduced tendency to use language that invokes the intentional stance (Knickmeyer et al. 2006).

So, if a male is slightly better at systemizing and slightly worse at empathizing, the extreme of this would be a person who was essentially disabled in terms of empathizing while preserving or even excelling at systemizing. This is what Baron-Cohen sees in people with autism: a severe impairment in the Intentional Stance, often accompanied by enhanced abilities underwritten by the Physical Stance.

Autism Assessment: The “Autism Quotient”

Autism is not necessarily a clean-cut distinction between those with and without the disorder. As the “extreme male brain” conceptualization suggests, if simply being male is a mild version of what it means to have autism, then there must be extreme and less extreme versions of autism.

Baron-Cohen and colleagues set out to design an instrument to quantify this tendency toward autism in normal populations. This instrument became known as the “Autism Quotient” or “AQ” (Baron-Cohen et al. 2001a). The AQ ranges from 0–50 and scores higher than the low 30s are considered to be extremely high, indicating Asperger’s Syndrome or High Functioning Autism.

The instrument is informed by a set of assumptions about the nature of autism, which has led to the assessment of five different areas: social skills, attention switching, attention to detail, communication, and imagination. The AQ shows a reliable difference between men and women, with men scoring higher. Scientists also reliably score higher than nonscientists, with mathematicians scoring higher than other professions.

Intervention

Baron-Cohen has also worked in the applied side of autism research, using an understanding of the interests and deficits common to people who he conceptualizes as more “systemizing.” He has authored DVDs intended to help people with ASD to recognize emotions, began the Cambridge Lifespan Asperger Syndrome Service (CLASS), and has investigated “LEGO therapy,” which uses the highly “systemized” LEGO toy to encourage social skills among individuals with autism.

Conclusion

Simon Baron-Cohen has had several major impacts on the study of autism and related disorders over decades of research, assessment, and intervention. Major contributions such as: the idea of mindblindness, the “extreme male brain” theory, and the Autism Quotient stand as noteworthy contributions to the field.

Lastly, for those who recognize the rather unique surname, Simon Baron-Cohen is, in fact, the cousin of actor and comedian Sacha Baron Cohen.

Definition

A family system headed by the female parent without the male parent physically in the home; male parent often offers little to no assistance in caregiving activities.

Introduction

Single mothers have been present throughout human history. Today, single-mother families are one of the fastest growing demographics with approximately 9.5 million families in the United States being headed by single mothers (Afifi et al. 2006). Because of the prevalence of single mothers, many researchers have tried to understand why mothers might have to raise their child alone, and the effects single-mother families can have on mother and child well-being. Some explanations of single motherhood are traced to sexual strategies. As with many other species where a mother has more parenting responsibilities, males might choose to mate with multiple women (Trivers 1972). As seen in birds, males might father multiple offspring with multiple partners, but will assist with rearing children with only one partner (Trivers 1972). Therefore, all other sexual partners who yield offspring will be left to care for their young without partner assistance.

While sexual strategies can lead to single-mother families, countries like the United States have also seen an increase in the number of families headed by single mothers because of cultural shifts leading to an increased social acceptance of divorce and single parenthood (Afifi et al. 2006).

However, while some mothers might become single parents because of divorce or partner absence, other mothers might have to raise children alone after the death of a partner or for other reasons. With increased interest in single-mother families, recent research has shown that it is important to make distinction between the causes of single motherhood because the cause for singlehood can have large influences on maternal and child outcomes ranging on maternal mental health, employment, and child behavioral development.

Causes of Single Motherhood and Its Effects on Mental Health and Employment

Mothers and children in two-parent households typically have more advantageous outcomes than children in single-mother households. In two-parent households, having two caregivers allows for more resources to allocate and higher levels of parental investment across children (Trivers 1972). Not having a second caregiver in the household can create strains on resources for in single-mother families that can lead to deleterious outcomes for both the mother and her children (Bilbarz and Gottainer 2000; Trivers 1972). Being a single mother can create emotional strains by increasing a mother's likelihood of developing a psychological disorder and financial strains because the loss of a second income might make it harder for a mother to maintain the basic physical needs of her family.

The absence or loss of a partner can create emotional strains which might limit a mother's ability to care for her offspring. However, the cause of single motherhood can create distinct differences in the mental health of the mother. Comparing married, never-married, and separated/divorced mothers, Affifi et al. (2006) found that the cause for single motherhood can significantly influence a mother's susceptibility to anxiety, mood, and externalizing disorders. Results found that separated/divorced mothers had significantly higher rates of anxiety, mood, and externalizing disorders than never-married mothers. Additionally, never-married mothers exhibited

very similar rates of anxiety, mood, and externalizing behaviors as married mothers who also had significantly lower reported scores than separated/divorced mothers (Afifi et al. 2006). These results could indicate that the social circumstances leading to separation or divorce might either place mothers at risk of developing psychopathology. However, because the present study does not examine the mental health of single mothers who are single due to partner death, this could potentially mean that other situational factors such as grief could further influence the mental health of mothers. The cause of single motherhood might not only influence a mother's emotional well-being, but might also influence her ability to financially provide for her offspring. This could further cause emotional strain and distress for the mother.

In western societies, research indicates evidence that it might be more financially advantageous for a mother to be widowed than to be divorced or never-married. In the United States, many widowed mothers are protected by financial statutes (such as Social Security) to provide some financial security for mothers and children after the death of her husband (Bilbarz and Gottainer 2000). In the case of divorced or non-married partners, the father might be instructed to pay child support, but this is not always guaranteed and can place single mothers and their children in financial jeopardy. While there might be some financial resources available for single mothers and their families, many single mothers, regardless of the reason why they are single, are required to enter the work force to provide for their families (Budig and England 2001). In a study comparing non-mothers to both married and non-married mothers, Budig and England (2001) found that while most mothers experience a 7% wage penalty per child, lifetime financial gain is seen to differ between married and non-married mothers. Reasons for the wage penalty across mothers could be due to extended leave to care for newborns, part-time work, and having to take more time off to care for sick offspring. However, for single or non-married mothers, the lifetime wage penalty is lower because she might have to work full time or forgo leave to ensure that she has the resources needed to provide for her family

(Budig and England 2001). While the financial needs of the family might be met, long periods of maternal absence can have large influences on child outcome.

Single-Mother Households and Child Outcomes

Household environment has a large influence on the developmental trajectory of children. Children who are raised by single mothers might have increased problem behaviors because of financial and emotional strains on the family. For some children of single mothers, this might lead to an increased influence of peer groups which can impact school performance and behavioral development (Steinberg 1987). The absence of the father in the household can also lead to biological changes in the child which can advance sexual maturation and lead to riskier sexual behaviors (Ellis et al. 2003).

Academic performance can have a large influence on later life trajectory by providing individuals with opportunities for financial and social advancement. Children raised by single mothers are seen to have decreases in academic performance compared to children from two-parent families (Lee et al. 2007). However, this effect is different between male and female offspring. In a study comparing families of single mothers to single fathers, Lee et al. (2007) found that high maternal involvement increased academic achievement in male children for reading and English test scores, but for female children, high maternal involvement was related to decreased performance in reading, English, and math scores. The opposite results were found for children of single fathers. Lee et al. (2007) posit that this difference might be due to children viewing their highly involved same-sex parent more as a peer than a parent. This could lead to diminished authority of the mother regarding the academic performance of her female children.

Though highly engaged single mother might have negative influences on female academic development, low parental involvement is typically shown to influence substance use and

antisocial behavior in children (Kuntsche and Silbereisen 2004; Steinberg 1987). In a study of Swedish 9th graders, Kuntsche and Silbereisen (2004) found that adolescents raised in single-parent homes engaged in higher levels of substance use behaviors. The results of this study might be explained by the financial strains caused from single motherhood that can cause a mother to spend extended periods of time away from the home. Extended absences can lead to weakened parent-child relationships and the increased reliance on peers. Steinberg (1987) found that adolescents who were raised in single parent households rated that they were more likely to engage in negative behaviors with peers (e.g., vandalism, drinking). While this could be related to the reliance on peers, these behaviors can also be driven by the parenting style adopted by single parents (Aunola and Nurmi 2005; Steinberg 1987). Single mothers are seen to engage in higher levels of high-control (often referred to as authoritarian) parenting styles (Kuntsche and Silbereisen 2004), and high-control behaviors are associated with higher levels of internalizing and externalizing problems for adolescents (Aunola and Nurmi 2005). Increased internalizing and externalizing behaviors place children at higher risk for engaging in antisocial behaviors. However, as with academic performance, research conducted by Steinberg (1987) and Kuntsche and Silbereisen (2004) indicate that there are sex differences in the outcomes for children of single mothers. Broadly, male children raised by single mothers are seen to engage in higher rates of externalizing behaviors than male children raised in two-parent households; females with highly involved mothers do not (Steinberg 1987; Kuntsche and Silbereisen 2004). Even though males engage in higher levels of risk-taking in general, males from single-mother homes still engaged in higher rates of risky behaviors than male children of two-parent families (Steinberg 1987).

Being raised in a single-mother household might not only increase the risk for externalizing behaviors in children, but father absence is seen to accelerate pubertal development of female children and place them at higher risk for risky sexual

behaviors and teenage pregnancy (Ellis et al. 2003; Quinlan 2003). In a cross-cultural longitudinal study, Ellis et al. (2003) found that females who had absent fathers had significantly earlier menarche, earlier first sexual experiences, and higher pregnancy rates than females of two-parent families. The results of this study found that these effects were magnified in female children who were in father-absent homes *before* they were 5 years of age – indicating that the timing of father absence might also be an important factor of development. However, when examining the effects of timing on internalizing and externalizing behaviors, timing was not a significant predictor, indicating that there might be alternate explanations for these increased behaviors in single-mother families (Ellis et al. 2003).

Conclusions

Single-mother families are one of the fastest growing demographics in society today. Even though single-mother families account for a growing number of families, research indicates that there are significant difficulties and stressors which can affect mothers and their offspring financially, emotionally, and physically. As shown in the research, coming from a single-mother household can place a child at specific risk for many negative outcomes. Further, research examining the timing of father absence on behavioral development might help with the understanding of the developmental outcomes of children raised by single mothers. With that in mind, it is clear that there are certain advantages afforded to offspring of two-parent families, and because the number of single-mother families is increasing, more research needs to be conducted to understand the preventative measures that can be taken to reduce the disparity in outcomes between children of two-parent families and single-mother households.

 Washington, Seattle, WA, USA

Synonyms

[Size](#): breadth, circumference, girth, height, length, mass, stature, volume, weight

[Dominance](#): influence, power, prestige, rank, status

Definitions

Size refers to relative organismal magnitude among conspecifics and is typically measured by somatic height, weight, mass, and volume, as well as length, width, and circumference of morphological traits. Among animals, larger body size often facilitates dominance, one's social rank attained via the use of force or threat of force.

Introduction

Size is among the most salient properties of biological organisms. An association of largeness with dominance and smallness with submission exists across species – exemplified by the common behavioral trait of manipulating one's apparent size through expansive or contractive gestures and, in humans, by the pervasive use of size terminology to denote status (e.g., “the high and the mighty” vs. “little people”) (Ellis 1994). In many species, dominance is associated with superior fitness outcomes, particularly among males (Ellis 1995), reflecting a legacy of selection favoring greater size, manipulations of size, and acuity to both. In humans, high social rank and rank-related reproductive benefits are attainable not merely through size and physical coercion, but also via prestige, status earned through perceived merit (Henrich and Gil-White 2001).

Selection for Size

Biological taxa often exhibit phyletic increase in size. This tendency is believed to result from the reproductive importance of organismal size despite costs attendant both to being and becoming large: greater food requirements, thermal stress, and conspicuity to predators, as well as the protracted vulnerability associated with slower growth, or the risky foraging and early reproduction associated with faster growth

(Blanckenhorn 2000). In fact, not only do larger-bodied individuals realize greater fitness than do smaller-bodied conspecifics across phylogenetically distant species, selection is stronger on size than it is on other morphological traits. Possible ecological selection pressures favoring large size include greater capacity to survive environmental variation, increased longevity, more efficient use of heat per unit volume, better ability to engage in or avoid predation, and reduction in mortality from superior resource competition and use (Kingsolver and Pfennig 2004).

Ecological selection pressures may also explain much intraspecific variation in size. As initially suggested by Darwin (1871) and supported more recently in a diverse array of anisogamous reproducers, selection often favors greater female size because of associated increases in fertility: larger females are often better able to procure resources, physiologically invest in offspring (e.g., in mammals via gestation and lactation), and produce ova of greater quality or in greater quantities (Andersson 1994). In some sequential hermaphroditic species, for example, individuals begin life as males but possess the ability to reproduce as females upon reaching a body size at which the costlier investment of female reproduction is advantageous. However, in many species, particularly among birds and mammals, males are larger than females. This is often the result of sexual selection, the evolutionary process that favors traits beneficial in securing mating opportunities (Darwin 1871). Competition for mates is generally more intense among males, for whom greater size may permit physical exclusion of same-sex rivals from mating opportunities and/or increase attractiveness to females (Andersson 1994).

Size and Dominance in Males

In humans, greater body size is associated with better fitness outcomes among men. For example, Mueller and Mazur (2001) found a positive relationship between height and reproductive success in a cohort of male military officers, attributable

to taller men's greater number of wives. Similarly, in a British cohort, Nettle (2002a) found that although taller men did not out-reproduce shorter men, they had more long-term relationships and were less often childless (though very tall men were more likely to be childless and have serious illnesses). Because men's height was better predicted by their fathers' social class than by their own social class, Nettle (2002a) attributed the finding to taller men's greater ability to secure long-term mates. Furthermore, Pawlowski et al. (2000) reported that taller men in their thirties, forties, and fifties were significantly more likely to be married and have children than were shorter men in each age group.

Men's height exceeds women's across populations (Gaulin and Boster 1985) and appears to be the product of sexual selection, a hallmark of which is appreciable sexual dimorphism that emerges at puberty. Males' 1% greater length and similar body fat percentage to females at birth (Wells 2007) becomes 7% greater height (Gustafsson and Lindenfors 2004) and 14% greater body mass in adulthood (Smith and Jungers 1997), largely as a result of males' pubertal increase in testosterone production.

One mechanism through which sexual selection may have favored male height is female mate choice. Females are predicted to be relatively discriminating in their mating decisions, and so the preferences of ancestral females may have shaped male stature. Consistent with this, studies of personal advertisements have shown females, but not males, to prefer tall partners, and taller males, but not taller females, to receive more responses. Similar results have been obtained in studies featuring greater ecological validity. Hill et al. (2013), for instance, found men's height to predict their attractiveness to familiar women when other sexually dimorphic traits were controlled, and in a natural fertility population from The Gambia, Sear (2006) found that while taller men did not realize greater reproductive success than did shorter men, they did have more marriages. This may reflect female mate choice for greater male height, or kin-mediated marriage decisions in which taller men have greater access to resources, possibly

by virtue of higher status. In addition to height, masculine male body morphologies are consistently associated with greater male attractiveness and mating success.

Selection pressures other than female mate choice may also have favored greater male size. For example, in an exploration of mating success among groups of social peers, Hill et al. (2013) found that body size (measured by a composite of weight as well as biceps, chest, and shoulder circumference) predicted number of sex partners in the previous year, a relationship not mediated by attractiveness to females but by physical dominance to males. Thus, men's mating success in this sample was predicted by success in male contest competition, a mechanism of intrasexual rivalry favoring greater size, strength, anatomical weaponry, and bellicosity that facilitates physical exclusion of same-sex rivals from mating opportunities. This research suggests that physical contests among men may have exerted stronger sexual selection pressure on human male traits than has female mate choice (see also Hill et al. 2017; Puts 2016). Indeed, U.S. presidents, many of whom have achieved their rank at least partly via dominance, have tended to be taller during times of societal threat and enjoy a wider margin of victory even with this variable controlled, suggesting that male height may be more valued when the perceived benefits of a dominant leader are believed most in need (McCann 2001).

Intrasexual contests also appear to have influenced male phenotypes among the other great apes (e.g., Wilson et al. 2014), whose male-biased sexual size dimorphism suggests that this trait may be phylogenetically conserved (Plavcan 2012). However, humans are more skeletally sexually dimorphic than their closest extant relatives, the chimpanzees (Gordon et al. 2008). In addition, sexual dimorphism in overall human body mass fails to capture men's appreciably greater muscle mass (Lassek and Gaulin 2009), which would likely have been attenuated in the absence of continued selection favoring it in antecedent hominins. Moreover, male-biased sexual size dimorphism among polygynous primates is

positively related to the intensity of mating competition, even with phylogeny and allometry controlled (Mitani et al. 1996).

Across a wide array of species, body size is associated with male dominance (Ellis 1994), and dominant males realize greater reproductive success (Ellis 1995). Being large or conveying cues to large size is thus an important determinant of fitness outcomes in animals. Indeed, exaggerations of apparent size such as low-frequency vocalizations are prominent among primates, including humans, perhaps because they create the impression of size with less somatic investment (Puts et al. 2014, 2016). In many primate species, dominant males monopolize sexual access to multiple females or disproportionately mate with those near ovulation. Across 13 species from 6 anthropoid genera, for instance, Cowlshaw and Dunbar (1991) found a positive relationship between male dominance rank and mating success with estrous females. Although inferences of fitness outcomes from mating behavior in nonhuman primates can be complicated by paternity uncertainty, genetic research has demonstrated positive relationships between male rank and reproductive success.

Male dominance and fitness also exhibit a consistent relationship in the human ethnographic record. Among the Yanomamo of Venezuela and Brazil, Chagnon (1988) found that *unokais* (warriors, or "men who have killed") realize greater reproductive success than do non-*unokais* as a result of both marriage and bride-theft. Becoming an *unokai*, an encouraged but voluntary duty, confers higher status on men, who list access to females as their primary impetus for killing. By contrast, men who consistently abandon inter-village raiding parties lose status, as evinced by the increased sexual attention from other males that the wives of such men receive. As with all traits, however, there are costs to physical aggression, the optimal level of which is therefore likely to vary across environments. For example, among the Ecuadorian Waorani, "a people even more warlike than the Yanomamo," the most zealous warriors experience poorer measures of fitness than do less zealous warriors (Beckerman et al. 2009).

Status in human males may be achieved not only as dominance via coercion, but also as prestige via elicitation of voluntary deference. Whereas dominant individuals are often feared and avoided, prestigious individuals are sought-after, emulated, and venerated because of their locally valuable knowledge and skills (e.g., in hunting), as well as their willingness to share these (Henrich and Gil-White 2001). For instance, among the Tsimane of Bolivia, von Rueden et al. (2008) found that men's knowledge-based skills and social support impacted the influence and respect they received among community members more than did their body size, though body size was the best predictor of peer assessments of men's ability to win in dyadic physical fights. Moreover, prestige-oriented status is associated with male fitness across small-scale human societies (e.g., Irons 1979). Prestige, however, does not appear to have superseded dominance in importance – both are viable means of acquiring and maintaining status in humans (Cheng et al. 2013). Indeed, among the Tsimane, both dominance and prestige have predicted men's surviving offspring, number of live births, extramarital affairs, number of serial marriages, wives' attractiveness, and number of allies and labor partners (von Rueden et al. 2011).

In addition to being distinct from dominance, prestige exhibits no clear relationship with body size. For instance, while male-biased sexual size dimorphism has been explained as the product of ecological selection via hunting (Plavcan 2012), a predominantly male activity associated with men's fitness in natural fertility populations (Gurven and von Rueden 2006), hunting is the most learning-intensive of all foraging behaviors (Kaplan et al. 2000), and return rates from hunting in small-scale societies often peak long after males peak in physical formidability (Walker et al. 2002). Thus, while hunting may have helped shape certain traits related to men's physical performance (e.g., Apicella 2014), relationships between hunting success and male fitness are most parsimoniously attributed to possession of knowledge-based skills. Moreover, the male-biased sexual size dimorphism inferred among some Pliocene hominin species (Plavcan

2012) reflects a greater antiquity in the human lineage than the emergence of hunting during the Pleistocene, and ecological selection leaves unexplained a suite of men's traits (e.g., facial hair, facial robusticity, and deep voices) that confer little benefit apart from aiding in male contests (Hill et al. 2017).

Size and Dominance in Females

As in males, body size is reproductively consequential in females of many species. In contrast to large males, however, large females often accrue fitness benefits through ecological selection for greater fecundity (Andersson 1994). In mammals, for example, selection favors females capable of gestating, lactating, and provisioning and protecting altricial offspring at least until weaning (Eibl-Eibesfeldt 1989). Human females appear similarly designed to invest physiologically in offspring. Women's body fat is essential for successful ovulatory function (Frisch and McArthur 1974), taller and heavier women have been shown to produce heavier offspring (e.g., Kirchengast et al. 1998), and maternal height is negatively related to offspring mortality, particularly in non-Western populations (e.g., Stulp et al. 2012). In women as well as men, moreover, height and mortality are negatively related (Jousilahti et al. 2000), though extreme height has been associated with reduced fitness and poor health in both sexes (Nettle 2002a, b).

Physiological investment in offspring is contingent on acquisition of resources such as food, to which dominance over same-sex conspecifics often affords females priority. Indeed, dominance and reproductive success are associated in females of many species (Ellis 1995). Across primates, benefits accrued by dominant females include higher-quality diets, earlier reproduction, faster reproductive rate, longer lifespan, and offspring that mature earlier and survive longer (e.g., Fedigan 1983; Harcourt 1987; Pusey et al. 1997).

While dominance and height are associated in females of many species, including humans, the association is often not as strong as it is in males

(Ellis 1994). In nonhuman species, this may reflect constitutional differences among females that permit some to achieve dominance more easily than others, or superior developmental diet and health, particularly in the case of inherited rank. In humans, females may compete more for access to long-term mates likely to furnish limited resources than for direct access to resources. As a result, sexual selection via contest competition has shaped the human female phenotype less than has male mate choice, which often appears designed to capture female physiological investment (Puts 2016).

Conclusion

In humans and across an array of animal species, organismal size facilitates and is positively related to dominance, or coerced social rank. While this relationship exists in both sexes, it is stronger among males, particularly in humans. Large individuals often receive priority of access to the resources most strongly constraining their reproduction: males to mates, food, and resources, females to food and resources. While alternative explanations have been posited, the aggregate of evidence suggests that, in humans, male size and body composition are the products largely of male contest-mediated sexual selection, whereas female size and body composition are the products largely of ecological selection for fecundity as well as male mate-choice mediated sexual selection. These conclusions have received support from diverse methodologies, species, and human populations.

Bipedalism; Human reproduction; Intrasexual competition; Sexual dimorphism; Size dimorphism

Definition

Sexual size dimorphism is defined as the physical size differences between males and females of a species. Whereas body size has traditionally been the most common measure, differences in the size of other features, such as canine teeth, as well as skeletal and cranial features are also used to measure the nature of Sexual size dimorphism in a species.

Introduction

Sexual size dimorphism (SSD) refers to the physical size differences between the sexes. Such size dimorphisms evolve as a result of natural and sexual selection and are closely linked to the nature of social and mating system in that species (Darwin 1871). Three major hypotheses traditionally explain how SSD may evolve: (1) SSD can arise through sexual selection if individuals of a certain size in one sex have better (or worse) reproductive success through mate choice and/or intrasexual competition. (2) SSD can evolve if larger females have better reproductive output than smaller females. (3) SSD can evolve when the sexes have adapted to different ecological niches in order to reduce intersexual competition. Research over the last decade suggest a more

Size Dimorphism

► [Size Dimorphism and Locomotion](#)

complex interaction of factors influencing survival (e.g., viability selection), reproduction (fecundity selection), and mating success (sexual selection) that shape the nature of SSD, because males and females often differ in each of these traits. There is considerable interest in understanding how and why SSD evolved in humans. Although intrasexual competition is popularly used to explain human SSD, a variety of factors, including intra- and intersexual competition, locomotion, and reproduction, appear to have contributed to SSD in humans.

Sexual Size Dimorphism in Hominins

Modern human males are on average 7% taller and about 15% heavier than females; they have broader shoulders, stronger musculature, and increased upper body strength compared to females. The modern human male skeleton is also more robust with heavier and larger bones. Male skulls are slightly larger with specific shape variations compared to female skulls. The human pelvis shows marked dimorphism in size and shape reflecting modifications for childbearing in females. Compared to extant nonhuman great apes, humans' SSD levels are low to moderate depending on what is being measured (Plavcan 2012). Most comparative studies use canine teeth and body mass in primates because they are more easily related to theories of sexual selection. Moreover, these traits are shared across primate taxa and thus are useful for comparative studies. Intense male-male competition is characteristic of great ape mating systems where there is selection on fighting performance. During male competition, canine displays are often cited to be aggressive signals; therefore, the lengths of the canines are used as a proxy for the intensity of male-male competition. Canine teeth dimorphism in humans is low compared to other primates. Total body mass is widely accepted to be the best indicator of SSD and also relates to male-male competition since larger males are physically more powerful and more successful in combat. They can also intimidate other males into submission without the need for combat. Compared to primates,

humans are only slightly more dimorphic than gibbons but slightly less dimorphic than chimpanzees (Plavcan 2012). Skeletal features are useful when comparing SSD to fossil data. Skeletal features suggest moderate stature dimorphism in humans compared to chimpanzees; skull SSD estimates are moderate, and postcranial (features other than the skull) estimates slightly exceed that of chimpanzees (Gordon et al. 2008). Overall, low body mass and canine SSD in modern humans suggest a reduction in the nature of male-male competition through human evolution. On the other hand, the moderate levels of SSD inferred from skull and postcranial stature would suggest that multiple factors influenced SSD in human evolution.

SSD in Ancestors of Modern Humans

The scanty human fossil record makes it very difficult to robustly assess SSD through human evolution. As observed in modern humans, most studies find that reduced canine size dimorphism is a typical feature of ancestral hominins (White et al. 2009) reinforcing the notion that male-male competition had reduced from that of chimpanzees. Skull, teeth, and postcranial estimates suggest very little SSD in *Ardipithecus ramidus* (~4.6 million years ago (ma)) (White et al. 2009) suggesting that male-male competition decreased early in hominin evolution. Estimates of SSD vary considerably across members of the genus *Australopithecus* (~4.2 ma), but the consensus indicates strong SSD in *Au. afarensis*, *Au. anamensis*, and *Au. robustus* (Gordon et al. 2008). Some studies claim humanlike levels of SSD (Reno et al. 2010). Size dimorphism appears to be strong in early *Homo* (~3.2 ma) in later *Homo* (see Plavcan 2012), as seen in *H. habilis* and *H. erectus* but then decreases to humanlike levels in later *Homo* (see Plavcan 2012). Overall, evidence suggests an intriguing trend with two major changes occurring through hominin SSD evolution, and both involve changes in female size. Given the apparent lack of SSD in *Ardipithecus*, strong SSD in *Australopithecus* was likely due to a decrease in female size (Gordon

et al. 2008; White et al. 2009; Plavcan 2012), and reducing SSD through later *Homo* likely occurred through substantial increases in female size. Inferring behavior from SSD data is in all likelihood speculative, but male-male competition alone cannot explain SSD evolution in humans.

Bipedalism and SSD: Intrasexual Competition and Male Body Size

Several hypotheses have been proposed to explain why bipedalism evolved in humans, including predation, foraging, thermoregulation, and energetics, but all of them invoke the overarching influence of environmental changes in the Miocene, which resulted in the disappearance of forests, and increased grassland. The demands of ecosystem changes likely influenced hominins to evolve energetically better locomotion to seek food and shelter in increasing savannah habitat and to reduce group sizes and intergroup distances in order to decrease competition for resources. Bipedal locomotion evolved early in hominin evolution. Strong evidence of bipedal features first appear in the pelvis of *Ardipithecus ramidus*, suggesting that members of the genus *Ardipithecus*, whose origins date back to the late Miocene (~5.8 ma), may have been partially bipedal (Haile-Selassie et al. 2012). Habitual bipedalism is widely observed through specializations in the feet, pelvis, and spine of *Australopithecus* (~4.2 ma). The spine reveals modifications to bear lumbar load during pregnancy – a feature not required in quadrupeds. Bipedalism provided a variety of advantages – from use of free hands, enhanced energetic, and ability to traverse craggy terrain – to the evolution of complex social behaviors.

Lack of significant canine dimorphism in hominins suggests that teeth baring was not relevant in competition, but body size must have been because males have maintained larger bodies through human evolution. During fights, all apes strike blows in a bipedal stance. Being able to stand upright not only frees the hands for striking opponents, but it also enhances fight performance by increasing range of motion and generating

more striking power (Carrier 2011). Moreover, humans are able to generate more force when striking downward, than upward, which could significantly affect the success of larger and taller males during combat (Carrier 2011). Being larger and taller would also have its advantages during hunting and obtaining mates. Almost all great apes are aggressive, and male-male competition for females can be intense and violent. Bonobos are an exception with lower violence. Ancestral hominins were no exception even if competition intensity had decreased. Moreover, male competition for mates is exacerbated in polygamous and promiscuous mating systems. Ancestral hominins were mostly polygamous. Even if they were like modern humans with serial monogamy, males would have competed for mates and resources.

Bipedalism and SSD: Selection on Female Size Through Reproduction

Fossil evidence suggests a decreasing trend of SSD through human evolution; SSD in *Australopithecus* resulted from a decrease in female size and then female size increased from early to late *Homo* (Plavcan 2012). If this is true, then clearly there was stronger selection on females relative to males. Theory suggests that there is typically a trade-off between body size, reproduction, and life history. Female fertility and fecundity is particularly important because their rates determine population growth and age structure, which can substantially influence life history traits, especially those associated with reproductive strategies.

In *Australopithecus*, while males may have maintained their size through competition, selection on smaller females were likely associated with early reproduction and fecundity due to early mortality and/or due to severe resource stress. Increasing female size from early to late *Homo* suggests selection favoring larger females either because they are outcompeting smaller females in a time of scarce resources or if larger females produced higher-quality offspring. It is possible that reduced mating competition and increased resource competition characterized later *Homo*. Resource scarcity will increase

mortality and thus exert pressure to decrease rates of early reproduction. Dominant resource-rich groups would have well-nourished females who could produce high-quality offspring. There are also suggestions that substantial ape-like to humanlike life history transitions, such as later age of first births, increased lifespan, and slower life history, all of which would increase female body size, occurred in later *Homo* (Robson and Wood 2008).

Another popular but intensely debated hypothesis, the obstetric dilemma, suggests that the female pelvis faced antagonistic selective pressures of bipedalism and birthing infants with large heads. This indirectly implies that selection may have acted against small statured women who are at higher risk of obstructive labor, which could explain increasing female size. However, recent studies reveal that bipedalism evolved under complex interactions between selection and drift and that a narrow pelvis is not required for bipedalism (Grabowski and Roseman 2015). Recent analyses also reveal broad pelvic canals in *Australopithecines* and even in later *Homo* (Gruss and Schmitt 2015). Moreover, pelvic dimorphism suggestive of any obstetric difficulties is not seen until *H. neanderthalensis*, and it was not until the late Pleistocene that the anatomically narrow pelvic canal evolved in *Homo sapiens* (Gruss and Schmitt 2015).

Another possibility that can influence female-specific changes in body size is maternal mortality in younger and in smaller females. Selection against early reproduction and smaller female size can result from male preference for younger women as mates. Given the shorter lifespan of ancestral hominins, it may not be unreasonable to assume that females reproduced at a relatively early age. If age of first birth in ancestral hominins is anything comparable to that in chimpanzees, which is 12–14 years, and if females of such age were developmentally unprepared for pregnancy (as they are in modern humans), then male mate choice would exacerbate selection against early reproduction, thus contributing not only to the increase in female size, but would also exert selection to extend age of reproduction. If dominant males can monopolize resources and mates,

and if these males preferred younger females, then male mate choice can accelerate the process of selection against smaller-sized females. However, this theory needs to be tested.

Conclusion

Current consensus is that a variety of factors, including sexual selection, natural selection, and environmental change, were involved in shaping human SSD. The magnitude to which each of these factors influenced SSD remains to be ascertained. Moreover, inferring behavior from fossil data is speculative. Early in hominin evolution, bipedalism may have contributed to intense male-male competition by enhancing fight performance, but resource scarcity driven by environmental changes likely influenced changes in hominin life and reproductive history traits. A large part of these changes appear to have occurred through modifications in female fertility and fecundity, which may have resulted in selection for larger females and thus reducing SSD in later hominin lineages. Much of these conclusions remain tenuous but also inspire more research to advance our understanding of human evolution.

Skew Theory

Joonghwan Jeon
 Kyung Hee University, Yongin, South Korea

Synonyms

[Optimal skew theory](#); [Reproductive skew theory](#)

Definition

An evolutionary theory attempting to explain the unequal sharing of reproduction among same-sex individuals within social groups.

Introduction

Cooperatively breeding animals vary markedly in reproductive skew, the unequal distribution of direct reproduction among same-sex individuals within social groups. In high-skew groups, such as eusocial ants, honeybees, termites, and meerkats, reproduction is concentrated in one or a few dominant individuals; in low-skew groups, such as some polistine and polybiine wasps and banded mongooses, reproduction is distributed more equitably among group members. Variation in skew frequently occurs both within and across species (Reeve and Ratnieks 1993; Vehrencamp 1983).

Reproductive skew theory aims to predict how members within a social group would partition reproduction in an evolutionarily stable way. To determine the optimal level of skew, it integrates genetic relatedness, ecological constraints on solitary breeding, group-living benefits, and within-group competitive asymmetries into a single theoretical basis (Johnstone 2000; Reeve and Ratnieks 1993). Further, skew models tend to, but not always, assume that each member's payoff of staying in the group should be greater or equal to the payoff of leaving to breed alone or fighting for the sole possession of the nest, thus opening up a new avenue for unraveling the evolution of group size and within-group conflict. Not surprisingly, researchers have boldly claimed that reproductive skew theory may be a good candidate for a general unified theory of social evolution, one that explains all the major features of all social taxa ranging from termite colonies to human societies.

Over two decades, a wide variety of skew models has been devised and the resulting predictions have been tested numerous times. The plethora of model variants with conflicting predictions, however, has attracted considerable skepticism and criticisms (Nonacs and Hager 2011). As a comprehensive literature review over various work and controversies on skew is beyond the aim of this entry, the basic models of reproductive skew and their implications for the humans are presented below.

Models of Reproductive Skew

Reproductive skew models can be classified into three major classes according to their different assumptions about how reproductive sharing is achieved within a social group: transactional models, compromise models, and synthetic models.

Transactional Models

Transactional models of skew assume that one individual has complete control over the partitioning of reproduction but the individual may “yield” a share of reproduction to other group members in order to maintain group stability (Reeve and Ratnieks 1993). Two types of transactional models exist: concession models and restraint models.

First, the concession model assumes that the dominant individual has full control over the reproductive partitioning within the group. Consider a group of two individuals, a dominant and a subordinate. If the dominant is too greedy and try to monopolize all direct reproduction in the group, the subordinate may choose to leave the group and reproduce solitarily. In response to the subordinate’s threat of departure, the dominant may concede just barely enough reproduction to the subordinate as an incentive to stay (Reeve and Ratnieks 1993; Vehrencamp 1983). The minimum share given to the subordinate would decline as (1) the expected reproductive success of a subordinate pursuing the departing option decreases (because, under harsh ecological constraints on solitary breeding, the dominant does not need to “pay” a large staying incentive), (2) the group’s overall productivity increases (i.e., the total size of the pie to be divided between the two has expanded), and (3) the genetic relatedness between the dominant and the subordinate increases (the subordinate’s indirect fitness payoff from remaining in the group increased).

Second, the restraint model assumes that the dominant only control group membership; that is, it has have the ability to evict the subordinate from the group (Johnstone and Cant 1999). It is the subordinate, however, who is assumed to have complete control over reproductive sharing. The subordinate may still exhibit a form of

reproductive restraint in order to avoid ejection from the group; it will thus obtain its maximum share of reproduction that can be tolerated by the dominant. Consequently, the concession and restrain models make exactly opposite predictions about the relationship between the genetic, ecological, and social factors and the level of reproductive skew.

Compromise Models

Compromise models do not incorporate the possibility of group dissolution. In other words, they assume that subordinates could not voluntarily depart the group, nor could the dominant forcefully evict subordinates. Another difference from the transactional models lies in whether any individual is assumed to have full control over the division of reproduction. In compromise models, no individual has complete control. Rather, each group member competes selfishly to gain a higher personal share of reproduction, at a cost to the overall productivity of the group. The partitioning of reproduction is determined by a compromise between the diverging optima of dominant and subordinates (Reeve et al. 1998).

The most well-known variant of this category, i.e., the tug-of-war model of Reeve et al. (1998), assumes that the dominant’s higher competitive ability renders it more efficient in converting its selfish effort to an increased personal share of reproduction. The evolutionarily stable level of skew is solved by finding the selfish efforts of dominants and subordinates in a way that the inclusive fitness of each is simultaneously maximized. The tug-of-war model yields different predictions from those of transactional models. The subordinate’s reproductive share at equilibrium would decline as the subordinate’s relative competitive ability decreases, but it will be quite insensitive to the genetic relatedness between the competitors. Ecological constraints, which were assumed away from the outset, would not affect the division of reproduction.

Synthetic Models

Synthetic models integrate the possibility of both group dissolution and incomplete control into a single framework. Each group member may

exchange reproductive payments to each other in order to maintain group stability, while simultaneously engaging in a tug-of-war competition over the remaining portion of reproduction (Johnstone 2000; Reeve and Shen 2006). Initial models, however, have been harshly criticized for theoretical shortcomings. For instance, it has been formally proved that a mixed strategy that involves both a tug-of-war and reproductive payments is unstable to invasion by a mutant “nicer” strategy that competes less strongly and gives a lesser reproductive payment (Cant and Johnstone 2009). Recent synthetic models attempt to overcome the stability problems of previous analyses, taking seriously the threat of departure/eviction or the power of negotiation.

Skew Theory Applied to Humans

Given that reproductive skew theory aspires to be a unified science of social evolution, it may be fruitfully utilized to elucidate the foundations of human sociality. Summers (2005) applied the classical concession model to the development of social stratification among human males. Recall that the concession model predicts that when group productivity benefits are greater, when the prospects for solitary breeding are lower, and when group members are more closely related, the level of skew within a group will be higher. Summers (2005) suggested that, since our divergence from the chimpanzee lineage, early hunter-gatherer societies were largely egalitarian (i.e., low level of skew) via the collective suppression of a self-assertive dominant individual by a group of subordinates. Around 10,000 years ago, strong ecological constraints on solitary dispersal, combined with the economically storable nature of agricultural crops, led to the formation of despotic preindustrial societies (i.e., high level of skew). For example, the harsh environments surrounding the Nile Valley made possible the development of extreme despotism in ancient Egypt. In the same vein, Betzig (2014) emphasized the role of ecological constraints in shaping despotic civilizations in Mesopotamia, Egypt, India, and China. Kings and emperors collected as many as

100,000 fertile women, whose children were supported by thousands of eunuchs (“sterile castes”). About 500 years ago, modern egalitarian societies emerged, the reason of which was attributed to the relaxation of ecological constraints, i.e., the discovery of two nearly empty continents (Betzig 2014).

In addition to human societies, the reproductive skew framework has been applied to analyze the extended human family. A growing body of evidence indicates that humans have evolved as a cooperatively breeding species, in which care and provisioning from family members from other than mothers were essential for child survival. Cant and Johnstone (2008) applied the tug-of-war model to understand reproductive conflicts between women of different generations. If female dispersal predominantly occurred in ancestral humans, there would be relatedness asymmetries between a mother and her son’s wife in the extended family. Although the mother is related to the offspring of the daughter-in-law, the daughter-in-law, by contrast, is completely unrelated to the mother-in-law’s offspring. Under these circumstances, the evolutionarily stable solution is for the old mother to commit to zero reproduction and allow the daughter-in-law to monopolize reproduction, leading to the evolution of menopause in human females. Empirical studies that tested Cant and Johnstone’s (2008) reproductive conflict model, however, have yielded mixed results.

Conclusion

Models of reproductive skew predict how reproductive conflict among same-sex individuals within a group will be resolved at evolutionary equilibrium, depending upon various factors such as grouping benefits, ecological constraints, genetic relatedness, group size, and competitive ability. The bewildering array of skew models, however, has recently met serious criticisms based on both theoretical and empirical grounds. Nonacs and Hager (2011) reviewed dozens of empirical studies across diverse animal taxa, concluding that neither relatedness nor competitive ability affected skew within a group. It thus

remains to be seen whether skew theory lucidly captures the true causes underlying the evolution of sociality. Nonetheless, skew theory has already done an important contribution on the study of cooperative breeding and reproductive conflict. For instance, the theory has rightfully highlighted that the possibility of group dissolution via departure/eviction has a great influence on how within-group conflict is resolved (Cant and Johnstone 2009). It is apparent that the studies of human kinship would also benefit by making full use of skew framework.

Skinner Box, the

Ioulia Papageorgi
University of Nicosia, Nicosia, Cyprus

Synonyms

[Lever box](#); [Operant conditioning chamber](#)

Definition

A laboratory apparatus developed by B. F. Skinner in operant conditioning experiments to study animal behavior, which typically contains a lever that delivers reinforcement in the form of food or water upon being pressed.

Introduction

The Skinner box (also known as operant conditioning chamber) was invented by Skinner while developing his theory of operant conditioning as a graduate student at Harvard University in the 1930s. It is used in the experimental study of animal behavior and allows the experimenter to manipulate, observe, and record an animal's behavior in response to environmental stimuli. Reinforcement delivery in the form of food or water is contingent upon a lever being pressed by the animal (usually a rat or pigeon). Responses are recorded on a cumulative recorder. The Skinner box and the cumulative recorder are two of Skinner's most important inventions in the experimental study of behavior and played a fundamental role in the development of operant conditioning theory.

The Skinner Box Design

Skinner may have been inspired to design his operant conditioning chamber by Thorndike's experiments using a puzzle box, which led to the development of Thorndike's Law of Effect (Thorndike 1898, 1911). The Skinner box is a soundproof rectangular box that contains a lever that, upon being pressed by the animal (e.g., rat or pigeon), delivers reinforcement in the form of food or water. In this controlled setting, a researcher is able to manipulate environmental stimuli and obtain a cumulative record of the animal's behavior from a device connected to the Skinner box, known as a cumulative recorder. This device produces a cumulative record in visual form, i.e., a graph that measures the total number of responses since the beginning of the experiment (Skinner 1959). Each response by the animal (rat or pigeon) moves a pen moving horizontally at a slow speed on a piece of paper one notch up, thus indicating vertically the number of cumulative responses recorded up to that point in time (time is measured in minutes and seconds horizontally). This design allowed Skinner to collect information on how different reinforcement schedules affect behavior (Ferster and Skinner 1957).

Uses of the Skinner Box in Research

The Skinner box has been used and is still being used by researchers as an apparatus in various areas of research. Indicative fields include testing the addictive effects of drugs (e.g., (Tirelli 1987; Pinkston and Branch 2004; Weaver and Branch 2008), animal cognition and learning (Shepard and Cooper 1982; Kentaro et al. 2002), memory and learning following brain damage (Nelson et al. 1997), and nutrition and its effects on learning and memory (e.g., Rojas et al. 2010). Researchers have gone as far as designing human Skinner boxes to study complex learning (e.g., Dibbets et al. 2002).

The Evolution of the Skinner Box in the Digital Era

Contemporary Skinner boxes retain the traditional 3D structure, but they are also connected to a computer through an interface. Behavioral responses are being detected electronically and they are recorded by a computer software. The presentation of the reinforcers (e.g., food or water) can also be programed with computer software. Some also include LCD screens to display digital images. Operant conditioning chambers in the digital era have evolved into computer controlled Skinner boxes (see for example Sokolowski and Abramson 2010).

Maintaining animal laboratories with operant conditioning chambers can be expensive (Graham et al. 1994). This poses a challenge for university professors who, in addition to the theory, aspire to give students hands-on experience of operant conditioning principles. To overcome such financial obstacles as well as the ethical dilemma of using animals for teaching purposes, software programs simulating operant conditioning chambers have been developed. Examples include *Sniffy the Virtual Rat* (Graham et al. 1994) and *EverQuest: The Virtual Skinner Box* (Yee 2001). More recently, open source devices such as the ArduiPod Box (Pineño 2014) have been introduced as low-cost alternatives to maintaining an operant conditioning chamber.

Conclusion

The Skinner box, an innovation developed by Skinner in the 1930s, has played a fundamental role in his experimental work on behavior and learning, which ultimately led to the formation of the principles of operant conditioning theory. The Skinner box has been widely used as an apparatus to collect information about animal behavior in response to environmental stimuli and reinforcers in various fields and areas of research. Contemporary versions of the Skinner box include computer-controlled operant conditioning chambers and virtual simulations.

Sleep-Wake Cycles

Christine Lalonde

Laurentian University, Sudbury, ON, Canada

Synonyms

[Circadian rhythm](#); [Master clock](#); [Molecular clock](#)

Definition

An endogenously generated daily cycle of approximately 16 h of wakefulness and 8 h of sleep

Introduction

Aside from nocturnal animals, humans, like many other mammals, sleep during the night, when the sun is below the horizon. Throughout sleep, metabolic processes are slow, activity is minimal, and consciousness shifts to a different state. Wakefulness generally occurs during daylight, characterized by high physical and mental activity, driving the consumption and utilization of large amounts of energy. The first glimpse of a biological driver of the sleep-wake cycle occurred in a fly, where the behavior was significantly altered when a gene was manipulated

(Wager-Smith and Kay 2000). Since then, both biological and psychological research have elucidated a complex feedback system that stimulates alertness in most animals and facilitates sleep. The circadian rhythm is one of the most conserved biological processes across a wide range of animals and is present in almost all human cells, controlled by a central regulator.

Brain and Function

The circadian rhythm is highly interconnected to metabolic processes and is controlled primarily by a regulator, the master clock, in the brain. The region of the master clock is called the supra-chiasmatic nucleus (SCN), within the hypothalamus, and contains about 20,000 neurons. The master clock receives input directed from the optical nerves in the eye, permitting “zeitgebers,” or environmental stimuli that signal daylight, to be perceived. Other signals, highlighting the relationship between organ systems, can stimulate and disrupt the sleep-wake cycle, such as food consumption or stress. The SCN, once stimulated, sends signals to the paraventricular nucleus (PVN) of the hypothalamus and activates the hypothalamic-pituitary-adrenal (HPA) axis. This pathway is responsible for stress signaling through steroidal hormones called glucocorticoids (GCs), as well as energy balance or metabolism (Nader et al. 2010). The PVN produces corticotrophin-releasing hormone (CRH), which is released into the hypophyseal portal system to bind to receptors in the anterior pituitary that initiates the secretion of adrenal-corticotrophic hormone (ACTH) into the bloodstream (Buckley and Schatzberg 2005; Garabedian et al. 2017). This stimulates the synthesis of the GCs cortisol (humans) or cortisone (rodents) from the adrenal cortex and, in turn, negatively regulates the HPA axis to control the concentration of circulatory GCs.

Glucocorticoids inhibit insulin production to prevent glucose from being stored in order to remain available for usage during a period of stress, whether it be exercise, mental focus, or infection. Circulating GCs act upon receptors in

almost all regions of the body except for the SCN itself. The master clock works through two antagonistic, self-regulating sets of oscillating genes, called a positive and negative limb, named for the activation or inhibition of transcription and translation (Zelinski et al. 2014). The clock genes, named CLOCK and BMAL1 (brain and muscle arnt-like 1), bind to form a heterodimer and induce the production of more genes, *Per* (period) and *Cry* (cryptochrome), which, in turn, downregulate CLOCK/BMAL1 and inhibit their own production. CLOCK/BMAL1 also induce another loop of circadian genes with *ROR α* and *REV-ERB α* , which bind to the BMAL1 promotor and counter-balance each other. With diurnal stimuli, this continuous loop leads to the oscillation of these circadian genes and the rhythmic expression of GCs through HPA axis stimulation. Without this complex system, GCs would be continuously released into the circulatory system, simulating a chronic stress state. These genes are present in almost all peripheral cells throughout the body and can be stimulated by GCs which can disrupt their natural metabolic cycle if the HPA axis has been activated in an acute or chronic state.

Disruption

Studies on shift workers detail a disruption in circadian rhythm signaling, including increased concentrations of GCs, into circulation during a period when they are typically suppressed (Karlsson et al. 2001). Along with the research on shift workers, investigations on disturbed light-dark signaling with animal models have correlated the chronic disruption in circadian rhythm signaling and GC patterns to the development of metabolic syndrome (Evans and Davidson 2013). Metabolic syndrome describes a cluster of disorders, such as low HDL cholesterol, visceral obesity, hypertension, insulin resistance, and increased triglycerides. A patient typically requires a diagnosis of at least three disorders to be categorized as metabolic syndrome.

Chronic sleep-wake cycle disruption has been linked to cognitive impairments, especially

with aging, such as depression, Alzheimer's, Parkinson's, and Huntington's disease (Musiek et al. 2015; Mattis and Sehgal 2016; Musiek and Holtzman 2016). Further disruption of sleep-wake cycles shifts the natural pattern of sleep; however, it does not necessarily interfere with sleep characteristics such as rapid eye movement (REM) sleep.

Evolution

Metabolism of resources are required to nourish organs and tissues, with a significant 30% going directly to the brain. The brain is known to process learned events during sleep, enhancing and storing memories as well as maintaining synaptic connections (Vorster and Born 2015). Predatory animals primarily hunt during the day, and as such, the theory behind sleeping at night serves as a multifaceted function – to conserve energy and to consolidate memory during a period when we are no longer active nor are threats to our survival as high (Berger and Phillips 1995). To conserve fewer resources, the master clock integrates the lack of daylight signals, and levels of clock gene expression are mostly inactive. GCs circulate at a significantly lower concentration, and most neural processes slow during sleep, except for survival functions and consolidation processes for memory. Energy expenditure is conserved with digestion slowing, body temperature dropping, and movement all-but-stopping. However, humans are not left totally unprepared to deal with a threat; if a startling situation were to occur, the fight-or-flight system would activate quickly, and energy stores would provide the energy required.

In addition to energy conservation, sleep-wake cycles have evolved to promote memory storage and enhancement (Kavanau 1997; Vorster and Born 2015). Sleep enhances the synaptic connections made during the day, intensifying what was learned. Numerous studies highlight the benefits of sleep; some have shown that subjects are able to recall more nonsensical information if they slept right after a learning session, and others have provided evidence in other learning tasks

and skills. Sleep can be seen in a wide variety of animal species; however, the evolution of memory consolidation in sleep seems to be convergent, considering the neural processes and characteristics of sleep among different animals, such as birds and reptiles, are quite different than those of humans and other mammals.

Conclusion

The evolution of the sleep-wake cycle and the master clock is conserved across many species; even though some have more or less genes involved, the system is intact in its structure and purpose. Not only does the circadian rhythm control metabolic and activity levels, but it also controls physiology, all through rhythmic gene expression. The system has evolved to control homeostasis and to either conserve or produce energy when required, but if dysregulated, it can disturb a cascade of physiological systems, ultimately leading to physical and mental disorders in humans.

Smarties Task, The

Simge Topaloğlu

Boğaziçi University, Istanbul, Turkey

Department of Psychology, Harvard University,
Cambridge, MA, USA

Synonyms

[Appearance-reality task](#); [Unexpected contents task](#)

Definition

The Smarties Task is a subtype of false-belief tasks that is used to test for theory of mind.

Introduction

The Smarties Task constitutes a by now classical paradigm often used in theory of mind experiments. In this procedure, children are shown a tube of “Smarties” (the brand name of a kind of chocolate candy) and asked to guess its contents. As expected, they typically reply by saying that the tube contains Smarties. Then the experimenter opens the tube, and it turns out that it actually contained an unlikely object (e.g., pencils). At this point, children may be confronted with two different situations: (1) a situation where they should state what another child (who has been waiting outside the room and did not witness the disclosure of the contents of the Smarties tube) would think the tube contained and (2) a situation where the child is asked what he or she initially thought the tube contained (Perner et al. 1987). Crucially, the first situation here requires the child to contrast his/her own current true belief (i.e., “the tube contains pencils”) with the false belief of another *ignorant* agent (i.e., “the tube should contain Smarties”), which is not different from what is found in other false-belief tasks, such as

the Sally-Anne task. The second situation, however, differs from other false-belief paradigms in that it requires the child to contrast his/her current true belief with his/her own past false belief. Perner et al. (1987) reported that children below age 4 failed in the first task where they had to attribute false beliefs to another person, while fewer children in the same age group failed in the second task, which was interpreted to mean that it was more difficult for children to reason about the mental states of others. The authors further explained this difficulty by saying that it must be hard for young children to assign two conflicting truth values to the same proposition (i.e., “the tube contains Smarties”) according to two different perspectives.

Variations

There are different versions of these appearance-reality tasks. While the Smarties Task may be the most famous one, there have been other influential paradigms that were similar to the Smarties Task in their underlying motivations and in what they tested. In a different experiment, for example, children are shown objects that deceptively look like another object at first sight (e.g., a sponge that is painted to look like a rock), and after the true identity of the object is revealed, they are asked to state either (1) what the object *looks like* and what it *really is* (an appearance-reality task, Flavell et al. 1983) or (2) what they thought the object was when they first saw it (a representational change task, Gopnik and Astington 1988). While the first study here focuses on whether children can discriminate between appearance and reality at a conceptual level, the second study is centered upon the question of whether children can scrutinize their erroneous past beliefs in the face of new evidence. The two lines of research converge toward the same findings, however. Flavell et al. (1983) found that 3-year-olds performed poorly in this task, while 4-year-olds were better, and 5-year-olds were virtually adult-like, showing that the appearance-reality distinction had not fully matured by age 3. Gopnik and Astington

(1988), on the other hand, found that 3-year-olds failed in the representational change task, while 5-year-olds succeeded at it. In this task, the object remained the same, while the child’s representation of it had to change (*rock* → *sponge*), so the child was required to ascribe two different representations to the same object over time. The authors attributed younger children’s failure to an inability to consider alternative representations of the same object, which they contend develops at around age 4.

It is notable, however, that notwithstanding the minor differences in the experimental designs and the results that were obtained, researchers’ explanations often point to an incapacity to represent conflicting truth values, perspectives, or representations as the most likely culprit for these error patterns. This suggests that some working memory and inhibitory control limitations might be playing a role in motivating the non-adult-like behavior in these explicit theory of mind tasks. Indeed, some studies have found a relationship between working memory and theory of mind, lending credence to this view (Gordon and Olson 1998; Carlson et al. 2002; Mutter et al. 2006).

Conclusion

Studies that employ the Smarties Task or similar paradigms have consistently found that preschool-aged children often have difficulties in discerning (or at least reporting) the differences between how an object is perceived by two different people, or by the same person at two different time points, or the differences between appearance and reality in general. While it is possible that children experience a conceptual change at this developmental stage whereby they become able to grasp that one object can appear one way but essentially be something else, or that different people have different perspectives, which may cause them to have different perceptions of an objective fact, it is also possible that children’s difficulties with this multifaceted thinking stem from immature general cognitive abilities.

Sneak Copulation

Lisa M. Danish

German Primate Center, Göttingen, Germany

Synonyms

[Hide and hurry](#); [Mate poaching](#); [Opportunistic mating](#); [Sneaking](#); [Surreptitious mating](#)

Definition

Sneak copulations are copulations that take place quickly, where the copulating pair attempts to remain hidden to avoid harassment and prevention of copulation.

Introduction

Sneak copulations occur in the following contexts in primates: 1) as an alternative to consortships (i.e., a short term mate guarding relationship) when consortships are harassed by higher ranking males (typically in species with shorter consortships), where females spend significant time not directly mate guarded (i.e., rhesus macaques *Macaca mulatta* Berard et al. 1994; Japanese macaques *Macaca fuscata* Soltis et al. 1997); 2) as an alternative to consorting when higher ranking males are able to monopolize access to females, typically while the male is distracted (i.e., mandrills *Mandrillus sphinx* Setchell et al. 2005; yellow baboons *Papio hamadryas cynocephalus* Alberts et al. 2006; olive baboons *Papio hamadryas anubis* Danish et al. 2014); and 3) as a means of gaining copulations with a pair bonded female (i.e., humans *Homo sapiens* Schmitt and Buss, 2001, gibbons *Hylobates* spp. Barelli et al. 2013).

Description

In seasonally breeding species, the high degree of female cycle synchrony in these species makes it difficult for males to monopolize access to females and reduces the benefits of mate guarding since mate-guarding males lose other mating opportunities (Berard et al. 1994; Soltis et al. 1997). As a result, females are not consorted all the time; however, lower-ranking males that attempt to consort are typically harassed; sneak copulations allow these males to avoid harassment. As expected with sneak copulations, even human observers may not see them; for example, subordinate male Japanese macaques (*Macaca fuscata*) are rarely observed to mate – but sire approximately half of the offspring (Soltis et al. 1997). In rhesus macaques, 45 % of known conceptions resulted from sneak copulations (Berard et al. 1994).

Males likely have fewer opportunities for sneak copulations when a female is continuously mate guarded (Alberts et al. 2006). Nevertheless, sneak copulations are observed in these species, though typically by adolescent males in the baboons and lower-ranking males in mandrills (Setchell et al. 2005; Alberts et al. 2006; Danish and Palombit 2014). Such copulations typically occur when the male is distracted by monitoring the group or even during an attempt by another male to oust the mate-guarding male. Sneak copulations result in little overall reproductive success in yellow baboons, however, with three adolescent males siring offspring using this tactic (1.4 % of 208 infants) (Alberts et al. 2006). Notably, the baboons live in an open habitat with high visibility, further reducing the success of this tactic; in mandrills, which live in a forest habitat, 27 % of infants are sired by sneak copulations (Setchell et al. 2005).

In species that are characterized by the formation of socially monogamous relationships and pair bonds, females are in longer-term mate-guarding relationships that continue beyond the fertile period (Schmitt and Buss 2001; Barelli et al. 2013). While gibbons and humans often live in pairs, extra-pair matings are observed.

Matings outside of the primary relationship are therefore sneaky by necessity and carry the risk of causing the cuckolded mate to abandon the relationship if discovered. Notably, both individuals engaging in sneak copulations may have primary partners. Although a majority of offspring are sired by the pair-bonded partner, sneak copulations do result in offspring (7 % for gibbons, up to 10 % for humans). In humans, behavior intended to attract a mate from an established pair bond is known as mate poaching. While mate poaching includes an attempt to permanently break the pair bond with the previous partner, it can also be a short-term event, relying on sneaky copulation.

Sneak copulations are considered an alternative mating strategy/tactic, as it is an alternative to the use of individual strength to obtain access to females (Setchell 2008). Low-ranking and extra-group males typically rely on sneak copulations, as they are unable to compete successfully with other males to obtain access to females. Sneak copulations comprised entirely of mating in response to a solicitation by a female are understood better as a female mating strategy. At least sometimes, however, males alter their behavior to take advantage of potential opportunities. Sneak copulations often occur on the periphery of the group, with females moving to the periphery of the group, suggesting the possible importance of female choice in this male strategy (Berard et al. 1994). Males either follow females after being solicited or wait for females on the periphery of the group. It is unlikely for a male to use successfully this strategy without female cooperation, since the success of the strategy is dependent on remaining inconspicuous.

The occurrence of sneak copulations is expected to exert selective pressure on higher-ranking males to more effectively mate guard fertile females (Schmitt and Buss 2001). The costs involved in mate guarding and synchrony of female cycles, however, constrain this counterstrategy. While sneaking generally is less successful than mate guarding, sneaking males avoid the costs of mate guarding and male intrasexual competition (Setchell 2008). Notably,

if sneaking is effective, the benefit to high rank – and therefore selective pressure to achieve such rank – is reduced. In addition, since sneaking results in multiple males mating with a fertile female, postcopulatory selection may be an important factor (Alberts et al. 2006).

Conclusion

Sneak copulations are an alternative mating strategy/tactic with variable fitness benefits; this variation may be due to differences in male effectiveness at mate guarding and habitat visibility (Setchell 2008). Sneak copulations, however, seem to be most effective in species in which high-ranking males are unable to effectively mate guard and the habitat has reduced visibility. Notably, in socially monogamous species, sneak copulations may be part of a mixed strategy, by which males with a primary partner obtain extra matings (Trivers 1972). When mate guarding is effective, sneaking seems to be a case of making the best of a bad job, allowing lower-ranking males to achieve at least minimal reproductive success. Sneaking is expected to promote sperm competition and select for increased mate-guarding behavior in higher-ranking males (Schmitt and Buss 2001; Alberts et al. 2006).

Sneak Copulation as an Alternative Mating Strategy

Charlyn Partridge

Annis Water Resources Institute, Grand Valley State University, Muskegon, MI, USA

Synonyms

[Alternative mating tactic](#); [Parasitic male](#); [Sneaker males](#)

Definition

Males that sneak fertilizations with females to circumvent direct competition with dominant males.

Introduction

Sneak copulations often occur as a way to circumvent direct competition with dominant or territorial males during mating. This gives males a chance to gain access to mates and increase their reproductive success, without the costs associated with aggressive interactions. Sneak copulations can be used opportunistically, or they can be the primary behavioral phenotype used by individuals either during a certain stage in their life or throughout their entire lifespan.

Sneaking as a Reproductive Tactics

In systems with alternative reproductive tactics (alternative behavioral phenotypes used to access mates, ARTs), the tactics typically consist of large “bourgeois” (dominant/territorial) males and smaller “parasitic” (sneaker) males (Taborsky 1998). Dominant males often guard territories and/or females within their territory during the mating period in order to prevent cuckolding by other males. In some cases, dominant males will directly compete with other males to maintain these territories or as a way of attracting females. Sneaker males, however, sneak fertilizations with females and avoid aggressive interactions with the dominant males.

Most of the sneaker tactics observed across taxa are likely components of a conditional strategy (Gross 1996). In game theory, a conditional strategy follows a decision rule where individuals that are condition A should perform behavior X, while those that are condition B should perform behavior Y. For instance, if large use a territorial tactic but if small use a sneaking tactic. However, the threshold condition that delineates behavior X and Y is likely to be genetically determined and show individual variation (Tomkins and

Hazel 2007). There are a few cases where a sneaking strategy is associated directly with a genetic polymorphism, such as the marine isopod, but this appears less common.

Sneak copulation behavior can be used opportunistically, associated with a specific life stage, or can be the predominant mating tactic used over the course of an individual's lifetime. One interesting species that exhibits a combination of these scenarios is the sailfin molly (*Poecilia latipinna*). In this species, male size is influenced by copy number variation at the melanocortin 4 receptor (*mc4r*) gene, and male size is highly associated with mating tactic (Smith et al. 2015). Small males predominately sneak fertilizations from unsuspecting females, while larger males predominantly perform courtship displays to attract females for copulation. However, males that are intermediate in size will switch between a sneaking and a courtship tactic, depending on the presence of other males in their environment (Fraser et al. 2014). When no other males are present, intermediate males will adopt courtship behaviors. However, when other males are present, these males will spend more time trying to sneak copulations.

Phenotypic and Life History Differences

In some species with ARTs, individuals may transition from one tactic to another either as they grow or in response to some environmental change. This transition can result in significant phenotypic and behavioral changes. One such example is the black-faced blenny. During the breeding season, sneaker males maintain a camouflage phenotype, while territorial males develop conspicuous coloration, consisting of a bright yellow body and black head. If a territorial male is removed from the area, a sneaker can change his coloration and take over that territory (De Jonge and Videler 1989). Utilizing a sneaking tactic early after reproductive maturation and transitioning into a territorial tactic once the individual can successfully compete for mating opportunities or resources is not unusual and has been observed in a number of species with ARTs.

While the above example included individuals that modify their behavior and morphology in response to an environmental change, some ARTs express these distinct phenotypes during the majority of their life. In dung beetles (*Onthophagus acuminatus*), there are significant differences in both body and thoracic horn size between territorial and sneaker males. Territorial males develop larger horns that are used in competition with other territorial males in order to defend burrows that contain females. However, sneaker males have a smaller body size and their horns are either reduced or even absent. Sneaker males avoid direct interactions with territorial males by digging alternative entrances to the burrow that intersect the main tunnel in order to gain access to the female (Emlen 1997). Body size, horn size, and tactic are dependent on larval diet, which can be experimentally manipulated by altering food quality (Emlen 1994). These territorial and sneaker morphs represent facultative developmental alternatives, where the body size and tactic assumed are regulated by a developmental switchpoint that is maintained throughout their lifetime.

Sneaker males can also have different life history traits compared to dominant males. This is seen in the bluegill sunfish (*Lepomis macrochirus*) and Atlantic salmon (*Salmo salar*). Sneakers of these species exhibit precocious maturation (i.e., they become reproductively mature at an early age). They also invest more heavily in reproduction relative to growth compared to territorial males. In bluegill, the testes of reproductively mature sneaker males represent roughly 4.5% of their total body weight compared to 1.0% for the parental (territorial) males (Gross 1982). Males in the precocious maturing life history do not transition into territorial males as they age. In contrast, they remain smaller than territorial males throughout their life and rely on cuckolding fertilization for their reproductive success. However, the average reproductive success of tactics associated with distinct life histories can be very similar, and these tactics may be maintained at an evolutionary stable equilibrium through frequency-dependent selection (Gross 1984).

Conclusion

Some males use a sneak copulation tactic as a way to increase their mating success while avoiding direct competition with dominant males. In some species, the use of a sneaking tactic can be opportunistic, while in others, this tactic is employed throughout their lifetime. Phenotypic and behavioral differences between males exhibiting a sneaking versus a territorial tactic can be striking. Sneaker males and territorial tactics may also be associated with distinct life histories.

Social Aggression

Kisha Radliff, Isabelle Shepp and Stephanie Flood
The Ohio State University, Columbus, OH, USA

Synonyms

[Indirect aggression](#); [Peer-to-peer aggression](#); [Relational aggression](#); [Relational bullying](#)

Definition

Social aggression is a broad term that generally includes relational (attempts to damage relationships or exclude others), indirect (behaviors, such as spreading rumors online, which do not occur in the presence of the victim), and nonverbal forms of aggression (e.g., dirty looks) along with verbal insults, the goal being to damage the victim’s self-esteem and social status (Ostrov et al. 2018).

Introduction: Theoretical Perspectives

Social aggression is used interchangeably with relational and indirect aggression throughout the literature; thus, it will be used as a broad term to represent all three forms of aggression. Several theories have been used to explain the development and maintenance of social, or relational, aggression; a few of these are briefly presented here.

Evolutionary theory provides the underlying context for understanding how the pressures placed on humans over time contributed to development of a system in which the expression of aggression serves a purpose, is valued, and

maintains the system (Godleski 2018). From this perspective, social aggression can lead to positive outcomes for the aggressor. Social dominance theory and resource control theory, which both integrate evolutionary theory, have also been linked to social aggression. Social aggression can be used to obtain and maintain social dominance over others within the same social setting (e.g., high school). Resource control theory provides context for why individuals who use social aggression may also demonstrate prosocial behaviors or strategies (Godleski 2018). Specifically, when social aggression is used in conjunction with prosocial behaviors, individuals are more likely to obtain the desired resources while also maintaining social status. The purpose of obtaining social dominance and gaining control of resources varies dependent upon age and setting. Examples include a child who befriends another child and uses coercive strategies (e.g., I won't be your friend unless you. . .) to gain access to something that child has (e.g., a special toy), an adolescent female who gossips and spreads rumors about the popular girl because she wants her boyfriend, and a man who feels threatened by a younger employee, so he attempts to socially isolate him by excluding him from social events and making demeaning comments about him to coworkers.

Who's Involved and What's the Prevalence?

There are several key players when looking at social aggression: the aggressor (i.e., bully), victim (or target), and bully-victim (those who are both socially aggressive and victimized). Additionally, there are bystanders who either watch and do not interfere in the bullying, defend the victims (defenders), or support the aggressor.

Prevalence rates for social aggression and other forms of bullying can be difficult to determine due to factors such as how the behavior is defined, level of frequency (e.g., two to three times in the past month) measured, length of time assessed, and the setting (Smith 2013).

There are some large-scale studies and meta-analyses that provide estimates. Cook et al. (2010) completed a meta-analysis on studies examining school bullying and aggression from several countries, including countries in Europe (42 studies) and the United States (21) and from other countries (16). The results revealed that, averaged across studies, 20% of students had bullied others, 23% of students were victims of bullying, and 8% were both bullies and victims.

The World Health Organization produces large-scale prevalence data from internationally representative samples of students (ages 11, 13, and 15) for school-based bullying based on the Health Behavior in School-aged Children (HBSC) surveys every 4 years. The 2009/2010 survey produced lower prevalence rates than Cook et al. (2010) with only 10.3% of students reporting that they had bullied others and 11.3% reporting being victimized. Data for bully-victims was not provided (Currie et al. 2012).

Through self-report measures and questionnaires, research indicates a steady decline throughout adolescence of those reporting being victims. The same decline cannot be seen when looking at self-reports of those who bully others; rather the type of bullying shifts from more physical in nature to more relational (Smith 2013). In considering sex and gender, boys and girls are closer to equal in the victim category, while boys are more prominent in the bully category. Additionally, the ways in which the bullying occurs may appear different between the sexes. Boys will likely engage in more physical forms of bullying, while girls center on relational bullying often fueled by ongoing feuds or opposing friend groups (Smith 2013).

Effects

Social aggression can have multiple negative effects on both the victims and bullies. Individuals who are aggressive have been shown to have both internalizing (e.g., anxiety, depression) and externalizing (e.g., defiance, impulsivity) behavior issues. Aggressors are more likely to be involved

in crime as adults and display conduct problems throughout adolescence (Holt et al. 2007). Victims have a higher risk of low self-esteem, school avoidance, and depression than their non-bullied peers (Holt et al. 2007). Both youth who are socially aggressive and youth who are victimized exhibit reduced social problem-solving, decreased emotional regulation, and increase peer issues (Leff et al. 2010). However, in some situations relational aggression may lead to popularity indicating that social aggression is a complex issue that needs to be fully understood in order to know how to best intervene (Leff et al. 2010). Those who are bully-victims are at the highest risk. These students may be the “provocative victims” or react strongly and aggressively to their own victimization. Bully-victims tend to be the most stigmatized by their peers and have a greater probability of being referred for psychiatric consultation (Holt et al. 2007).

In addition to those directly involved in the bullying process, there are also those in the roles of bystanders, including defenders and supporters. Research indicates that a student’s role as a bystander is largely influenced by both individual and social factors. Defenders are more likely to display personality traits such as altruism, agreeableness, and a prosocial orientation and often have high self-esteem and productive coping styles. Bystanders who just watch may have a fear of being the next victim or feel uncertain about how to intervene (Nickerson et al. 2008). Many bystanders will express feelings of disgust, sadness, or anger at bullying and aggression, while few do anything to intervene. Understanding the social phenomenon of the bystander effect has been a focal point of research for social psychologists for decades (Nickerson et al. 2008).

In extreme circumstances, experiencing social aggression can lead to school or work avoidance or even suicide if the individual becomes hopeless. Hinduja and Patchin (2010) examined the links between bullying, cyberbullying, and suicide. The authors found that middle school students who were engaged in cyberbullying or in-person bullying as the victim or bully showed increased reports of suicidal ideation and suicide

attempts in comparison to peers that did not experience or engage in cyberbullying or bullying. However, students who were victimized showed the highest rates of suicidal ideation and behaviors (Hinduja and Patchin 2010). It can be argued that the effects of social aggression are just as, if not more than, harmful as physical aggression.

Prevention and Intervention

In general, the programs that target social aggression have numerous important similarities: they are developmentally appropriate for their audience, and they tackle relational aggression from a systemic approach, teach social problem-solving skills and leadership strategies, and take a multilevel approach (such as involving the teachers and/or parents; Cappella and Weinstein 2006; Leff et al. 2010). It is also important to consider factors such as social aggression in romantic relationships and in the cyber-world when identifying an intervention and considering objectives (e.g., what skills are taught). As technology is advancing, social aggression is taking form via cyber or electronic communication. Youth are no longer free from aggression in their own home; instead they can be subjected to these interactions 24/7, necessitating a program that addresses cyber-forms of social aggression (Hinduja and Patchin 2010).

Schools can take a systematic approach to address social aggression by implementing intervention and prevention efforts at three levels: school-wide, in individual classrooms or small groups, and to individuals. The same approach could be used in the work setting implementing interventions across the company, within a department, or for individuals. At the school-wide level, key personnel with knowledge regarding evidence-based interventions, such as the school psychologist and principal, can determine what intervention or prevention programs are appropriate for their school (Leff et al. 2010). It is critical that the program is monitored through data collection to determine its effectiveness. *I Can Problem Solve* is a school-wide program that has

teachers implement a curriculum focusing on teaching prosocial and problem-solving skills. In addition to formal programs, strategies such as increasing supervision at recess, establishing bullying policies and disciplinary measures, and parent training or involvement have been shown to be effective aspects of prevention and intervention (Ttofi and Farrington 2011). Bullying policies and disciplinary measures were found to be correlated with less bullying overall; however, there is no evidence that these policies had positive effects for bullies or victims individually, demonstrating the need for targeted interventions (Ttofi and Farrington 2011).

Intervention can also be implemented at the small group level, which allows for specific interventions (e.g., conflict resolution skills) to meet the needs of identified students. There are many programs that exist to prevent and/or intervene regarding social aggression at this level such as Second Step and Social Aggression Prevention Program (SAPP; Leff et al. 2010). By implementing evidence-based social emotional learning programs such as SAPP, issues related to social aggression can be targeted and addressed. For example, Cappella and Weinstein (2006) examined the effects of implementing SAPP for girls in fifth grade and found increased empathy and increased social problem solving as an outcome of the program. They also found that girls identified as being high-risk for social problems had more positive outcomes (Cappella and Weinstein 2006). Lastly, schools can intervene on an individualized level with individuals involved in social aggression by determining the area of need and selecting an appropriate evidence-based intervention.

Overall, policies addressing bullying and social aggression and prevention and intervention efforts that teach social problem-solving and prosocial leadership and include parent involvement have been shown to have positive outcomes. Generally, the longer and more intense intervention or prevention programs result in greater outcomes (Ttofi and Farrington 2011). Programs that allow people to practice these skills and to be given feedback over a consistent duration of time are essential.

Conclusion

Social aggression is a complex event that is used to manipulate and damage relationships, cuts across settings (e.g., schools, cyberspace), and leads to negative outcomes that range from mild to extreme. While consistent prevalence rates of social aggression are difficult to establish, it is clear that this is a problem affecting many youth and adults and can have negative, even dire, consequences for the individuals involved. Addressing social aggression through evidence-based prevention and intervention efforts, especially for children and adolescents, is of paramount importance.

Social Anxiety

Leif Edward Ottesen Kennair¹ and
Thomas Haarklau Kleppestø²

¹Department of Psychology, NTNU – Norwegian University of Science and Technology, Trondheim, Norway

²Department of Psychology, University of Oslo, Oslo, Norway

Synonyms

Social anxiety disorder; Social phobia

Definition

Social anxiety disorder is a marked fear or anxiety about one or more social situations in which the individual is exposed to possible scrutiny and negative evaluation of others. The social situations almost always provoke fear or anxiety, and the social situations are avoided or endured with intense fear or anxiety (American Psychiatric Association 2013).

Introduction

Other people have been our primary psychological selection forces. As species, hominins were selected socially and sexually, and as such, other people have both been our primary competitors and our greatest resources. We are therefore especially interested in evaluating other people, considering their emotional states, their personality traits, and considering what resources or threats they might be for us.

The need to socially belong is one of the fundamental human motivations (Baumeister and Leary 1995). Hence, we would expect the evolution of psychological adaptations that regulate and express this desire in adaptive ways. Social fear and anxiety might serve the function of inhibiting social behaviors that put humans at social risks, for example, by inhibiting other aspects of human nature, such as mate poaching, stealing, cheating, and murdering. Fear of social sanctions might adaptively inhibit these behaviors (Buss 1990).

For an hyper social species such as humans, losing the support of others or being disliked by other people in our group would have been devastating to our ancestors' fitness (Buss 1990). Ostracism would probably result in becoming an evolutionary dead end. Fear of negative evaluation is therefore not surprisingly something that concerns many, if not most, people. Fear of negative evaluation is naturally the hallmark of social anxiety disorder. However, only 12.1% of the US population develops debilitating symptoms that warrant a diagnosis of social anxiety disorder during their lifetime (Kessler et al. 2005). Furthermore, The risk is higher for females, and the disorder typically has

an early onset, often beginning in childhood or early adolescence (Stein and Stein 2008).

Different Theories of the Evolution of Social Anxiety Disorder

Öhman (1986) proposed one of the earliest, and most comprehensive, models of social anxiety disorder from an evolutionary perspective. His perspective is that we are prepared through selection to fear specific stimuli. In the case of social anxiety, the stimuli are dominant and aggressive conspecifics. Angry faces are therefore important social stimuli. Social anxiety is therefore considered part of a prepared submissiveness learning system.

Trower and Gilbert (1989) also proposed a model of social anxiety in which people evaluate conspecific threats, and that activates a dominance hierarchy mind set. This means that humans have psychological adaptations that assess and protect against hostility from others with submission and appeasement. The idea is hence that social anxiety reduces the chance that social conflicts will escalate into fitness-damaging violence and catastrophic social exclusion. This theory shares some foundations with the social competition hypothesis of depression, namely, to protect against aggression from others.

Finally, Stein and Bouwer (1997) suggested the false appeasement theory of social phobia, which also is about defending against social aggression from others. In this model, social phobia is considered to result from severely exaggerated appeasement displays, especially blushing, when such is not called for by the social context. Social anxiety is hence viewed as a dysregulated activation of otherwise adaptive features.

Leary and Jongman-Sereno (2014) provide an update of one of the most developed accounts of social anxiety disorder from an evolutionary perspective, based on self-presentation theory. This perspective expects social anxiety to be elicited when people are not confident that they will be

able to make the desired good impression on others. The self-presentation perspective may be extended with sociometer theory, where the relational value of others needs to be considered, when predicting when a social context elicits social anxiety.

General Discussion of the Theories

Most of the theories above are based on normal social anxiety being an adaptive, social relationship regulating mechanism, while full-blown social anxiety disorder is a harmful dysfunction. This might be true. However, people seem to be popular even when very low on social anxiety. The social dominance aspect might therefore be relevant, a position most of these approaches promote. The problem of the above theories is largely a lack of correspondence with how social anxiety presents. If the adaptive value of social anxiety is to prevent social ostracism, then we should not find extroverts more socially attractive, and socially anxious people should not be excluding themselves from society and their in-group by having fewer relationships, marrying later, having less education, and receiving fewer promotions. It is important to note that there is little evidence that people who reduce their social anxiety run the risk of social attacks or exclusion. Reducing safety behaviors improves social functioning; avoidance promotes continued anxiety. There is therefore little evidence of adaptive value to current social anxiety disorder (Kennair 2007). The lack of empirical work to convert these theories into practical and evidence-based mental health interventions is a general problem within evolutionary clinical psychology.

Further, as we saw in the introduction, social anxiety disorder is by no means a human universal, which we would expect if social anxiety disorder were in itself an evolved adaptation. Most people do not experience these symptoms during all of their life, even though the social situations that tend to activate crippling fears in people with social anxiety disorder are part of the general human experience.

A Cognitive Therapy Approach

None of the current evolutionary theories of social anxiety disorder have made it fully into mainstream clinical theorizing or practice; they are more or less familiar as just-so stories with little practical value. Current effective treatments such as Clark and Wells (1995) cognitive model stress how patients create exaggerated negative images of themselves based on the intropection of anxiety symptoms. The patient thereafter assumes that peers will evaluate them negatively due to how they appear. To reduce the impact of the anxiety symptoms, patients engage in unhelpful symptom concealing and safety behaviors, including social avoidance. Reducing safety behaviors and providing patients with more realistic feedback of how they appear seem to reduce symptoms efficiently. In addition, the therapist helps the patient discontinue worry about how one appeared in social situations. People with less social anxiety worry less about negative evaluation of others. A normal interest in how others perceive oneself is probably helpful for socially intelligent interaction with others; overly negative assumptions about how others perceive one based on faulty perception and worry are probably not adaptive. Evolutionary approaches might become more relevant if they incorporate the functional knowledge about maintaining mechanisms and efficient treatment within mainstream mental health care.

Conclusion

It is likely that many human emotions and motivations have evolved to solve evolutionary problems that inevitably arise when living in groups. The acquisition of social status, mates, friendships, and other alliances requires adaptive regulations of social emotions and behaviors. The adaptive theories of social anxiety may therefore be useful if they generate testable predictions about human nature that can be a key in understanding why people are vulnerable to develop social anxiety disorder.

Different evolutionary approaches to social anxiety disorder have been proposed focusing on the threat of dominant conspecifics and exaggerated appeasement or submission. These have not largely influenced mainstream mental health care or research. Future evolutionary considerations of social anxiety disorder might benefit from addressing the functional models found in efficient therapy.

Social Authority

Bin-Bin Chen
Fudan University, Shanghai, China

Synonyms

[Dominance](#); [Leadership](#); [Power](#); [Social rank](#); [Social status](#)

Definition

Social authority is an individual or institution that has legal power and control in a social system or makes decisions and enforces rules.

Introduction

In hunter-gatherer societies, living in a group is more adaptive than living alone. Groups are better able to cope with natural disasters, such as earthquake and famine, and social problems, such as fighting against intruders and predators, than

individuals. Thus, in the evolutionary past - and in contemporary human societies - being a member of a group had survival value and offered reproductive advantages (Baumeister and Leary 1995; Kenrick et al. 2010). In addition, members of a group may encounter recurrent problems that not every member can solve alone. These problems create pressure and circumstances favorable to the emergence of a social authority composed of experienced individuals who can lead and help other group members to solve problems. Following a social authority may benefit group members.

The Emergence of Social Authority

The situation, processes, and qualities (SPQ) model was originally used to explain the emergence of leadership (Spisak et al. 2011) but can also be used to provide an account of emergence of social authority. The adaptive challenge of social authority comes from the demands of authority “situations” (the S factors). In any situations, there needs authority “processes” (the P factors) to promote the benefits of a group. A social authority process is any behavior related to the exercising of legal power and control or the making of decisions and enforcing of rules. Last, social authority “qualities” (the Q factors) should be considered in order to determine whether there are individuals who can execute these behaviors. This model is consistent with the evolutionary hypothesis of stable individual differences in the emergence of social authority. But future empirical studies should be conducted to test these hypotheses based on the SPQ model.

Conclusion

In summary, an individual’s survival and reproductive opportunities are enhanced by living in a group that obeys a social authority. It should be noted, however, that there is less empirical literature dealing with social authority from an evolutionary perspective than there is in the case of related constructs (e.g., social dominance, status, power and leadership). The evolutionary origins

and functions of social authority are not fully understood. In addition, there is no unified or general evolutionary model of social authority. One way of exploring social authority involves distinguishing it from related concepts (e.g., social dominance, status, power, and leadership). The challenge for evolutionary psychologists is to generate better explanations of social authority.

Social Categorization by Age of Faces

Denise M. Barth, Bradley D. Mattan and Jasmin Cloutier
University of Chicago, Chicago, IL, USA

Synonyms

[Age perception](#)

Definition

Chronological age refers to the number of years since birth that an individual has been alive. Age can also be discussed as a category, however, with individuals belonging to a group of people whose chronological age falls within a specified range (i.e., age group). For example, youth as an age group may include anyone with a chronological age between 0 and 30 years old. Ultimately, age groups are social constructs and may vary by culture.

Social categorization refers to the classification of other individuals into particular group memberships based on characteristics deemed meaningful by society. Examples of social categories include age group, sex, and race. Social categorization based on age can lead to stereotypical and evaluative biases. One of the central ways by which we categorize age is through examining the facial characteristics of others.

Introduction

Social categorization is instrumental to our understanding of others and, accordingly, much research has been dedicated to elucidating its mechanisms. Building on theoretical models of face perception, investigations have focused on understanding the categorization of faces based on three fundamental social categories: age, sex, and race. Of the existing research on these social categories, the social cognitive processes specific to age categorization have received the least attention. However, there is reason to believe that age categorization is in many ways distinct from sex and race categorization. For example, over the life span, one's age group changes (e.g., from childhood to young adulthood; young adulthood to middle-age, etc.). This is not typically the case for one's sex or racial group. Age group transitions are reflected in featural changes in the face and body (Wiese et al. 2013). Such featural changes may shape perceptions of someone's age category, ultimately influencing our motivations and experiences with that person. Although we often categorize others based on age through

the perception of particular facial features, the process of age categorization from faces is influenced by additional information available about others, including other social categories.

Categorization by Age of Faces

Faces represent particularly rich sources of information about others. Together with prior knowledge about a person, they can reveal an individual's age, gender, race, identities, emotional states, current mental states, and even general traits such as trustworthiness or dominance. Due to the unique range of knowledge we can extract from them, researchers believe that humans are adapted to become face experts from a young age (see Simion and Di Giorgio 2015 for a review). Possibly as a result of our extensive exposure to and experience with interpreting faces, it is believed that faces may be processed by dedicated neural processing in comparison to other frequently encountered visual objects.

Evidently, it seems that social categorization from faces arises not only as a result of one's experiences, social environment (i.e., social norms, intergroup contact), and attempts to understand others, but is also tied to particular cognitive and neural processes. Indeed, we can categorize others even more efficiently than we can recognize them (Cloutier et al. 2004) and evidence shows that we spontaneously categorize faces by age (and other categories) with little effort (Montepare and Zebrowitz 1998). Furthermore, we are particularly efficient at estimating age from faces based on features such as skin (texture and elasticity) and hair (color and quantity) (Rhodes 2009).

Function of Age Categorization

Although social categorization is relatively efficient, categorization based on age is not inevitable when we encounter others. Perceivers may categorize an individual based on one category in lieu of another, and doing so may have particular evolutionary functions. For example, whether a

perceiver preferentially attends to someone's age or sex depends on which social category (i.e., age or sex) is more important in shaping our behavior toward that person. For example, young adult perceivers spontaneously attend more to age when categorizing infants, but attend more to sex when categorizing young and old adults (Cloutier et al. 2014). Given that sexual maturation of facial features does not occur until well beyond infancy and that infants' age should guide adult behaviors towards them to a greater extent than their sex, knowing the infant's age can be more useful than knowing the infant's sex. In contrast, perceivers may primarily attend to the sex of younger adults as it represents the age period when reproduction is most likely. Thus, the social category we primarily attend to may depend on which is most functional (i.e., useful to know). As a consequence, the ability to categorize based on age may provide the means for determining who requires care (e.g., infants, children, elderly) and when reproduction is viable (e.g., young adulthood) (Neuberg and Sng 2013).

Consequences of Age Categorization

Even if social categorization allows us to efficiently navigate our social environment, it is not without negative consequences. While categorization from faces can be quite accurate and faces themselves provide perceivers with a wide range of information, the information we infer may not always be correct. That is, humans can be prone to error when forming impressions about others from faces. Not only do we tend to have better recognition for faces of people from our own age group (known as the Own-Age Bias; Wiese et al. 2013), but we also often exhibit evaluative and stereotypical biases towards other-age individuals. Generally, older individuals are perceived negatively and stereotyped as low in cognitive ability and competence (Cuddy and Fiske 2002). In contrast, young people are generally perceived as possessing greater ability and promise than older people. These stereotypes often emerge and are applied unintentionally, yet can have

negative external consequences for the members of a given social group. Discrimination can emerge against elderly individuals systematically (i.e., medical or work settings; see Cuddy and Fiske 2002 for review) as well as on an individual level (e.g., interactions with younger family members or caretakers; Ryan et al. 1995).

Because faces provide information about multiple social categories and traits, it is important to consider how age categorization unfolds when other attributes of the person are known. As is the case with evaluative biases, stereotypic age biases can change as a function of the race or gender of the perceived individual. Thus, stereotypes associated with any one dimension alone may or may not apply to different-age individuals. Rather, stereotype activation, in addition to categorization, is sensitive to the context and social expectations we have about others.

Conclusion

While the exact functional constraints shaping age categorization remain to be determined, it is without a doubt one of the social cognitive tools recruited to help us make sense of our social environment. We can efficiently and accurately extract age from facial cues, and the process of age categorization subsequently impacts our evaluations, judgments, and interactions with others. Nonetheless, age categorization and its social consequences can be highly influenced by context and other category memberships such as sex and race. Given that aging is an unavoidable aspect of the human condition, it is necessary to continue investigating age categorization in order to better understand its function, its impact on person perception and evaluation, and the consequences it has for others.

Social information processing

Definition

Processing information on other agents, their relations and interactions, necessary for social behavior and group living.

Introduction

Social cognition is a broad range of processes underlying agents' ability to identify, represent, and respond to other agents and groups, their behaviors, intentions, and relations. It covers many aspects of human cognition, such as perception, memory, attention, to the extent that they refer to social stimuli, but also deals with some more specific phenomena: social categorization, biases and stereotypes, imitation, Theory of Mind, or emotions. In a broad sense, social cognition encompasses affective processes as well perception, memory, or reasoning. The traditional division between cognitive and affective sides of human subjectivity was challenged by Damasio (1994) and is currently not considered as a fundamental and objective division. Instead, they can be seen as a set of closely connected and interdependent processes. As opposed to behaviorism, which considered human mind as a “black box,” the theory of social cognition seeks to

identify those processes and mechanisms, which serve as an intermediary between two objective and observable sets of phenomena: that of the brain (and sometimes body) functioning, and that of behavior.

Although social cognition is only a part of cognitive abilities, it is considered as a special domain, which is responsible to many uniquely human abilities and the foundation of human social life. Currently, there are several key issues in the study of human social cognition: its evolutionary origin, the relations between sociality, and the evolution of cognition; the uniqueness of human social cognition; the composition and structure of social cognition. Below, these issues are considered in more details.

Social Cognition as an Adaptation

The key assumption of evolutionary psychology is that all sustainable aspects of human mind and behavior evolved as the adaptations to specific environmental challenges. The same is true about social cognition. According to evolutionary perspective, any specific social cognitive ability, which can be identified in humans or other species, such as communication, imitation, social categorization, etc. should be considered as a response to ecological or social environment and problems of their ancestors. These abilities are supposed to increase individuals' and/or groups' fitness and, in the long run, reproductive ability.

Although the general idea of adaptive advantages of social cognition is widely accepted, there is no consensus regarding the exact list of challenges and selective pressures fostering the evolution of specific cognitive abilities as well as on the very list of such abilities. Some researchers only point to cooperation and competition as two main tasks involving the need for specialized social cognition skills (Platt et al. 2016). Others discuss a wider and more complicated range of social domains, in which evolutionary pressures toward the development of social cognition exist. According to Kaschak and Maner (2009), there are four such domains challenges:

1. Self-protection. The fundamental need for protection includes protection from social threats, i.e., other individuals or groups, and, correspondingly, the need for abilities to rapidly identify and evaluate such threats.
2. Social affiliation. Living in groups implies social inclusion, cooperation, and social exchange, which require the ability to identify interpersonal relations and group membership, and control for possible social exclusion.
3. Mating. Mate selection and protection of relatively long-term relationships, necessary for successful reproductive strategies, foster the abilities to identify and evaluate potential mates and rivals.
4. Status/Power. The necessity to increase access for resources and avoid conflicts with more powerful individuals may lead to the development of cognitive skills of fast and accurate recognition of social hierarchy.

A slightly different list is provided by Ackerman et al. (2012). In addition to four challenges similar to those described by Kaschak and Maner (interpersonal aggression, affiliation, status, and mating), they add two more:

5. Disease avoidance. Potential dangers of social contacts are not limited to violence and aggression but also include contagious diseases. The ability to correctly identify cues of potential risks to one's health can thus be considered as another element of social cognition.
6. Inclusive fitness. Authors consider kinship as a special type of social relationship, differing from affiliation and requiring specific psychological mechanisms, fostering unconditional altruism, and prosocial behavior.

It can be seen that these extended lists of evolutionary challenges are not unique for humans or even other "social" species. Many species have to manage kinship or power relations, not to say of self-protection or mate behavior. At the same time, there is a wide consensus that humans' abilities for social cognition are far more advanced than that of other species including primates. This means that applying evolutionary arguments to human social cognition, one needs to argue that

their early ancestors faced some unique combination of selective pressures or that some emerged new adaptations gave them important advantages in comparison to other species. These two possible factors underlying the uniqueness of human social cognitions are not necessarily contradicting and may reinforce each other.

When evolutionary psychologists try to identify specific features of human social life as a source of unique social cognition ability, they mainly point to its enormous complexity (Freeberg et al. 2019; Dos Santos and West 2018). This complexity is not simply the size of groups, in which humans live. Many species live in groups including hundreds and thousands individuals. What is more important is the diversity of individuals and group types, their complex internal structures, and the multitude of relationships within and between groups. Even in archaic human societies, individuals have to correctly represent this complexity to solve practical problems. For example, the universal task of self-protection needs advanced cognitive skills in complex groups as compared to simple ones. To correctly evaluate the potential threats from other individuals, one has to take into account not only their physical conditions and current activities but also relations to others, possibility to recruit allies, affiliation with the different groups, long-term goals and strategies, and the needs for cooperation. Additionally, human affiliation and hierarchy are multidimensional, diverse and flexible. Any individual can be affiliated with numerous groups: families, clans, political or religious organizations, local communities, work- or hobby-related groups, contextual associations, etc. Even the basic kinship relations in archaic societies are subjectively complex and managed by fine-grained sets of rules, albeit implicit (Bourdieu 1980). Social hierarchies are based on various types of unequally distributed resources: physical ability, money, competences, political power, reputation, and so on. To manage the diversity of social affiliations and hierarchies, one has to properly recognize and represent them as well as construct complex models of interactions including this diversity. As a result, some researchers propose that the very notion of social complexity

should include the use of cognition as its defining feature (Bergman and Beehner 2015).

Although navigating the complex social world of human societies is cognitively challenging and requires exceptional skills, this doesn't mean that human social cognition is a direct consequence of this complexity. The very development of such complex societies would be impossible without appropriate social abilities. Thus, it would be more accurate to say that human social cognition evolved in interaction with the evolution of societies and culture (Dos Santos and West 2018). The unique social environment of human societies is thus insufficient to describe the uniqueness of human social cognition as such.

Sociality and the Evolution of Human Cognition: Four Hypotheses

In explaining what is uniquely human in the cognition of our specie, or arguing the very existence of such uniqueness, two general approaches can be proposed: general and adapted (specialized) intelligence (Herrmann et al. 2007). The first one implies that the evolution of humans and primates in general are associated with increased general cognitive skills resulted from larger brain-to-body size ratio. Larger brains allow to store more information, make more complicated and efficient computations, predict and plan better, and learn faster. Although larger brains are more energy-consuming, they provide benefits in solving practical daily tasks such as foraging, navigation, self-protection, and so on. According to this view, human social cognition might be simply a by-product of such greater cognitive abilities as they allow to better recognize and store information about different social agents, reconstruct their goals and develop own strategies, operate with cultural symbols, etc.

In support of the general intelligence hypothesis, Reader et al. (2011) analyzed data on 62 primate species and found that various ecological, technical, and social capabilities, such as social learning, innovation, and tool use, coevolved and are all a part of a composite measure of general intelligence. They also revealed that high level of

general intelligence evolved independently in four different lineages (capuchin, baboon, macaque, and apes) in response to various ecological contexts, and that social complexity was not a good predictor of both general intelligence measure and laboratory cognitive performance.

Alternative approach suggests that the evolution of exceptional cognitive abilities of humans is a result of more specialized adaptations. There are three main hypotheses specifying these adaptations, not necessarily mutually exclusive: ecological, social, and cultural intelligence.

The ecological intelligence hypothesis explains the evolution of human cognition as a response to specific ecological contexts, in which our ancestors lived. This hypothesis is in line with the fact that many different species developed very advanced, highly specialized cognitive skills necessary to solve specific tasks. Ethologists provide numerous examples of exceptional capabilities of many non-primate species including birds, fishes, lizards, and insects, in perception, memory, navigation, computation, learning, or communication tasks (Shettleworth 2010). In these specific tasks, they can easily outperform humans or other primates.

When speaking about primates, their specific cognitive capabilities are typically associated with foraging demands and particularly the use of tools and object manipulations (Parker and Gibson 1977; Rosati 2017). The initial argument was that primate species living in more demanding ecological contexts developed adaptations necessary to use tools and manipulate objects for feeding purposes. Recent studies focused on a more extended list of capabilities necessary to exploit rare and high-value food resources by primates (MacLean 2016; Rosati 2017). For example, Rosati (2017) compared cognitive performance and ecological contexts of two primate species, which are closest human relatives, bonobos and chimpanzees. Having equally complex social organizations, they demonstrate important differences in cognitive abilities and behavior. Particularly, chimpanzees have better spatial memory, larger preference for delayed rewards, and larger preference for more rewarding but risky choice. The two species are also characterized by several

social features: chimpanzees are more aggressive and have more intense male-to-male bonds, whereas bonobos rely more on female bonds and are more tolerant.

These differences, both cognitive and social, are thought to result from various ecological pressures and feeding demands. Briefly, chimpanzees live in more demanding environment and depend on more patchy fruit resources. On the contrary, the bonobo's diet is based on more evenly distributed food resources (herbs). Chimpanzees' feeding strategies, to be successful, should be based on spatial memory and more costly behaviors, including the use of tools and hunting. Importantly, ecological factors are considered as the source of both nonsocial and social cognitive abilities and behavior. Chimpanzees' ecological context demands a more individualistic behavior with greater feeding competition, although still allowing for contextual cooperation. In turn, bonobos, with their reduced aggression and intolerance, are more cooperative. Comparing bonobos and chimpanzees is crucial for understanding human social cognition, as these two living species are considered as the best models for the reconstruction of the last common ancestors of humans and other apes. Although both species share distinctive features of human social cognition, increased cooperative abilities and communication skills seem to be especially crucial for human sociality (MacLean 2016). What is important for the ecological intelligence hypothesis is the assumption that the initial drive for the necessary adaptations, including hormonal regulation, sexual dimorphism, or social cognition, was the ecological context and selective forces, which were, in fact, nonsocial by nature.

Comparative analysis regarding six species of lemurs also showed the interrelation between specific ecological context, types of sociality, and cognitive differences (Rosati 2017). Particularly, species relying on more frugivorous diet have significantly better spatial memory and motor control as compared to species with more folivorous diet. At the same time, as regards specifically social cognition, purely ecological explanations may seem incomplete. Some lemur species relying on mixed diet were found

to differ in some aspects of social cognition depending on the type of sociality: ring-tailed lemurs living in large groups have significantly better gaze following and transitive interference capabilities as compared to mongoose lemurs living in pairbonds (Rosati 2017). Thus, contemporary views on ecological intelligence confirms the significance of nonsocial ecological factors in the evolution of human cognition but also bridge the gap with the main rival hypothesis, that of social intelligence.

The social intelligence hypothesis (also known as Machiavellian intelligence) is the major alternative to both the general and ecological intelligence hypotheses. It argues that it is exactly the social environment and social complexity, which is responsible for unique cognitive capabilities of higher primates and especially humans. Studies of primates, conducted in the second half of twentieth century challenged the view that the evolution of human mind was primarily associated with tool making and use. They showed that primates had complex and diverse social life and shared many specific social features which were traditionally thought as uniquely human, such as establishing coalitions, deception, reconciliation of relationships after conflicts, reciprocation of help in contests, and other (Byrne 1996). As a result of these studies, a new theoretical framework explaining the origin of human cognition emerged under the umbrella term “Machiavellian Intelligence” (Byrne and Whiten 1988; Whiten and Byrne 1997). Richard Byrne and Andrew Whiten, two main proponents of this approach, describe its core idea as “the implication that possession of the cognitive capability we call ‘intelligence’ is linked with social living and the problems of complexity it can pose” (Whiten and Byrne 1997, p. 1). The term “Machiavellian” is used to stress that human social behavior is not simply based on self-interest but also that in pursuing own goals individuals develop complex and elaborated strategies, in which this self-interest can be well camouflaged and presented as altruistic behavior. This means that social life fostering cooperation and prosocial behavior can be more efficient in terms of reproductive success than more obviously egoistic

behavior, when individuals live in complex groups with high degree of interdependence.

Proponents of the Machiavellian Intelligence hypothesis agree that the ecological context poses serious problems which can favor specific cognitive adaptations. However, they stress that the social environment has some unique features triggering faster cognitive evolution. Unlike most nonsocial environmental pressures, changes in cognitive abilities directly change the social environment itself. Increased intelligence among some social agents gives them advantages in competition, thus leading to increasing cognitive capabilities across the whole population.

Social complexity is the key factor affecting the evolution of the social intelligence. It is not reduced to the number of individuals in a group but rather deals with the complexity of social relations among them and the variety of social behaviors expressed by individuals. Species living in relatively complex social environments, often use subtle social tactics. For example, a female baboon can spend time and efforts for grooming a sole male to establish affiliative relations with him, with the goal of receiving support in further contests (Byrne 1996, p. 174). Different forms of complex social tactics of establishing short- or long-term alliances, hierarchies, competition involving third parties, deception, and others were found in both primates and other species such as zebras, lions, hyenas, dolphins, etc. Such tactics would not be possible without specific cognitive abilities: correct identification of conspecifics, their position in a social structure, good memory for their personal histories, attention for social information, and visual perception. Social complexity is thus thought to select for better memory, effective learning, and processing of social information (Byrne 1996, p. 175).

Further development of the approach was the idea of the “social brain.” According to it, greater social complexity requires more computational capabilities, which, in turn, need larger brain and brain-to-body size ratio. Of a special importance are neocortical areas of the brain involved in cognitive mechanisms of reasoning and consciousness, which are crucial for social cognition. An analysis performed by several researchers,

particularly Robin Dunbar, showed a relative neocortical size in 24 anthropoid primates as strongly correlated with the group size (Dunbar 1998). Importantly, the neocortical size was not correlated with the type of diet or other possible indexes corresponding to the logic of the ecological intelligence hypothesis. The social brain hypothesis implies that the brain, and especially neocortex size, determines the information-processing capacity necessary to maintain complex social relations and the cohesion of a group. The so-called Dunbar number (roughly equal to 150) determines the number of social contacts, which can be effectively managed by the human brain.

Equally important for the social brain hypothesis is the idea that the brain size as such is not sufficient to understand the evolution of human cognition. The type of cognitive processes supported by it is even more important. The social brain is not simply about memory; the key specialization of neocortical areas is mental representation capabilities, and especially “theory of mind,” i.e., the ability to understand and reconstruct others’ mental states and intentions. Such abilities, more developed in apes than in monkeys, are a distinctive feature of human cognition and are necessary to develop fine-grained strategies of the “Machiavellian” type.

Although now widely accepted, the social intelligence hypothesis is not free from criticism. Kay Holekamp (2007), comparing various species, points to several problems of this theory. For example, some non-primate species, such as spotted hyenas, live in as large and complex social groups as many primates and demonstrate the comparative variety of social capabilities including processing complex social information, memory for conspecifics, their affiliations and rank, reconciliation after contests, and so on. At the same time, the primates’ greater intelligence, cognitive flexibility, and learning capabilities may indicate that such social complexity is not sufficient to explain the cognitive evolution. Other facts also seem to contradict the social intelligence hypothesis. Bears, which are solitary species, have larger brain and neocortex, are more innovative and flexible as compared to most gregarious

carnivores, e.g., hyenas. Even more remarkable is the fact that great apes have some unique cognitive capabilities (social learning and mentalizing) as compared to monkeys, although they live in groups of similar size and complexity. Recognizing these facts, the proponents of the social intelligence idea hypothesized that other, nonsocial selective pressures (e.g., the need for greater representational abilities to manage more complex feeding environment) might contribute to the cognitive evolution of primates and humans (Byrne 1996). As a result, integrative views on cognitive evolution recognizing both social and ecological factors are currently considered as a more appropriate explanation (Holekamp 2007; Rosati 2017).

The Cultural Intelligence Hypothesis can be considered as an advanced version of the social intelligence hypothesis, focused almost exclusively on the evolution of human mind. Some researchers use the term “ultra-sociality” to stress the exceptional cooperative abilities necessary to maintain human societies (Tomasello 2014). The evolution of human cooperation is considered as a two-step process. First, ecological pressures associated with reduced availability of food resources forces early humans to cooperate intensively. Second, such cooperation extended beyond kinship and included larger social groups. In turn, the need to cooperate within large groups required large-scale solidarity and identification. Such large social groups are in fact cultural groups as their existence relies upon symbols and institutions, which mediate and structure social interactions. Living in cultural groups requires specific skills to learn and operate with symbolic objects necessary to interact with others and acquire knowledge (Tomasello 1999). The hallmark of human symbolic communication and learning abilities is language. Although human language shares many common elements with animals’ communication systems at the neural level (Seyfarth and Cheney 2014), it is significantly more complex, and culture is thought to stimulate fast biological adaptations for the development of language (Thompson et al. 2016).

The cultural intelligence hypothesis argues that early symbolic cognition necessary to live in large

cultural groups are responsible for human exceptional cognitive abilities in general. To test this hypothesis, an international group of researchers compared performance of human 2.5 years children, chimpanzees, and orangutans in a large set of physical and social cognition tests (Herrmann et al. 2007). They found that, across various tasks in the domain of physical cognition (e.g., locating a reward, discriminating quantities, tool use), chimpanzees and human children did not differ in their performance, and orangutans performed only slightly worse. On the contrary, in the social domain (e.g., social learning, understanding communicative cues, gaze following, etc.) human children significantly outperformed both species of apes. The results were interpreted as supporting the cultural intelligence hypothesis and contradicting the general intelligence hypothesis. If the later was true, we might expect that human children would outperform apes in both social and physical cognition tasks. Authors supposed that the crucial developments of social cognition occurred not earlier than one million years ago and became the response to the needs of complex forms of cooperation during foraging. Again, confirming the potential role of nonsocial ecological factors in the development of human sociality, the cultural intelligence hypothesis is not incompatible with other versions of the adaptive intelligence approach.

Uniquely Human Social Cognition

The approaches explaining the evolution of human mind, briefly described above, differ in the role they ascribe to social environment as a driving force of this evolution. Among them, the cultural intelligence hypothesis is the most interested in understanding those aspects of cognition, which make humans unique specie. Comparative research in the evolutionary biology revealed that social cognition is widespread in the nature and many cognitive abilities traditionally considered as uniquely human are shared by different primate and non-primate species. At the same time, the difference between the complexity of human societies and animal group living is enormous. This

poses an important question of what exactly are those social cognitive abilities, which support the human “ultra-sociality.”

The cultural intelligence hypothesis was the closest to answering this question. The study by Herrmann et al. (2007) mentioned above not only concluded that human children are better in social cognition tasks than great apes but also specified the nature of these differing capabilities. In only one of six social tasks used by the researchers, there was no difference in performance. In this task, participants had to make a pointing gesture to receive a hidden reward. In all other five tasks human children performed better, and the difference was especially high in a social learning task (learning how to solve a problem by observing how is it solved by another individual). These results indicate that the ability to learn from others and, to a lesser extent, to identify their internal states and communicative abilities are especially important to deal with the social complexity of human societies.

Rebecca Saxe identifies two aspects of social cognition, which are assumed to develop in childhood and be responsible for complex social behavior: attention to faces and the representation of triadic relations (Saxe 2006). First, although sensitivity to faces and basic skills of mentalizing are common for both humans and apes, the ability to differentiate between the actual state of affairs and its representation by others develops only in humans. This means that the ability to represent and reconstruct others’ representations (rather than simply goals or intentions) is a uniquely human aspect of social cognition. The second distinctive feature is the ability to represent triadic relations between Oneself, the Other, and an Object: unlike apes, human children are able to understand others’ communicative gestures (e.g., when the Other points to a hidden reward). According to Saxe (2006), these uniquely human aspects of human cognition are supported by two specialized brain systems: temporoparietal junction (Theory of Mind construction) and medial prefrontal cortex (triadic attention).

The black-and-white view on the mentalizing abilities as uniquely human was recently challenged, when advanced forms of mentalizing

were found in apes and other primates in more natural competitive contexts (MacLean 2016). The abilities for deception and manipulating others are consistent with the Machiavellian Intelligence hypothesis and are thought to be crucial when competition is sharpened. Instead, researchers supposed that what is more specific for human is a combination of perspective-taking skills with a cooperative motivation to share one’s mental states with others, i.e., advanced communication (Tomasello et al. 2005; MacLean 2016).

Exceptional cooperative needs and interdependence of human societies, as well as living in large groups, stressed by the cultural intelligence hypothesis, have three important consequences for human social cognition (Tomasello 2014). First, to cooperate in socially complex and diverse contexts, humans must be able to construct alternative perspectives and representations of a situation, which can even be contradictory. Second, to develop long-term cooperative strategies, they must be able to make recursive social judgments and reconstruct others’ perceptions of one’s mental states and intentions. Third, they must be able to represent group norms and evaluates own and others’ behavior in terms of them, – which is a direct consequence of high interdependence between individuals. Moral reasoning is thus a necessary aspect of human social cognition and rationality necessary to cooperate in large groups.

The Structure of Social Cognition

What the evolutionary approaches share is the assumption that all human cognitive abilities including social ones should be understood as adaptations to specific situations, in which our ancestors lived. Correspondingly, it is reasonably to consider any specific element of social cognition as an adaptive response to specific evolutionary challenge. The structure of social cognition, i.e., its specific elements, processed and/or abilities, should thus reflect the nature of ecological and social problems typical in the earlier stages of human and/or primates ontogeny. One attempt to describe the structure of social cognition as a set

Social Cognition, Table 1 Correspondence between evolutionary problems and the structure of social cognition. (Adapted from Kaschak and Maner 2009, p. 1237)

Social domain	Evolutionary problems	Social cognitive processes
Self-protection	Avoiding social threats	Automatic and fast attention to angry faces and other cues of social threat
Affiliation	Gaining acceptance by a group; regulating social exchange; helping others with minimal costs	Identifying with a group, estimating degree of social closeness (e.g., kinship-based); vigilance to potential cues of social exclusion
Mating	Evaluation and selection of mating partners; relationship protection	Sensitivity and attention to physical attractiveness; vigilance to attractive rivals
Social hierarchy	Gaining high status; avoiding conflicts with high-ranked individuals	Representation of hierarchical relations and attention to status symbols

of adaptive responses was provided by M. Kaschak and J. Maner (see Table 1).

Although attempts to directly deduce the expected social cognitive processes from the retrospectively reconstructed evolutionary challenges can be useful, this is not the only possible way to understand the composition of social cognition. Studies in social psychology and social neuroscience provide a view on human social cognition without a direct reference to the problem of its evolutionary origin.

At present, there is no consensus in social psychology and social neuroscience on the exact list and interrelations of social cognitive processes as well as the degree of their specificity for the “social” realm. Many researchers provide significantly varying accounts on what social cognition consists of and on the scope of phenomena covered by this term.

For example, Fiske et al. (2007) proposed that social cognition can be understood in terms of two underlying fundamental dimensions: warmth and

competence. These dimensions reflect the perception of key issues of social life, competition/cooperation, and status. Jointly, the two dimensions describe representation of any social agent and specific emotions and behaviors toward them. This approach considers the basis of social cognition in social perception. Even more importantly, the fundamental aspects of social cognition are thought as typological, i.e., social agents are perceived in terms of their common, universal traits rather than their individuality, intentions and goals.

Other researchers extend the domain of social cognition far beyond such typological processes. A review by Happé et al. (2017, pp. 244–245) describes several such taxonomies:

- Individual recognition, knowledge of others' relationships, and theory of mind (Seyfarth and Cheney)
- Affiliation/attachment, social communication, self-perception, perception and understanding of others (National Institute of Mental Health)
- Affiliation, agent identification, emotion processing, empathy, individuals' information store, mental state attribution, self-processing social hierarchy mapping, social policing, ingroup/outgroup categorization (Happé & Frith)

The authors themselves described eight elements of social cognition (Happé et al. (2017, p. 247):

- Affiliation and social motivation (regulating approach-avoidance behavior)
- Agent recognition (identifying others' individuality)
- Motion perception, action recognition, and imitation (identification of actions made by others)
- Emotion recognition
- Empathy (mirroring emotional states of others)
- Social attention (conscious or automatic)
- Social learning (learning from others)
- Theory of mind

This list of cognitive processes used by the authors is obviously incomplete, as it does not include such important elements of social

cognition as the representation of social hierarchies or social judgments. However, the authors used this list not to reconstruct the general structure of social cognition but rather to illustrate how the different processes can be related to each other. For example, imitation, empathy, and theory of mind can all recruit one common process, self-other distinction, which can be thus considered as their foundation.

Another theory, considering social cognition as a construction of subjective social reality, distinguishes between the three general elements: direct input of social information from a given situation (e.g., by observing others' behavior); extracting relevant information from memory; variety of operations, both automatic and controlled, performed with these two types of input information (Greifeneder et al. 2018). Whereas many other psychologists and neuroscientists study basic, lower-level processing of social information, the authors are more focused on high-level social cognition involving complex social constructs and operations, such as stereotypes, scripts, priming, social judgments, etc.

Unlike psychologists, social neuroscientists attempt to identify key elements of social cognition by distinguishing underlying neural systems and processes. For example, according to Gallese et al. (2004), there are two similar but distinct neural mechanisms based on mirror neurons (specific type of neurons, which are activated both when an individual perceives others' actions and perform the same actions) involved in social cognition. They are responsible for our understanding others' actions and emotions. In its core, social cognition is fundamentally individuated, whereas any typological representations (e.g., representation of social groups or status) should be considered as relying upon these basic abilities to imitate other individuals.

An integrative model proposed by Yang et al. (2015) identifies three basic components in the neural system of social information processing: social perception (decoding others' mental states based on face expressions and behavioral signals); action perception (imitating others' actions with the mirror neuron systems); and theory of mind (high-level cognitive ability to represent other's

mental states and intentions necessary for strategic planning).

One of the most detailed map of social cognitive processes is provided by Lieberman (2007) who identified four broad areas of social cognition processed by distinguishable neural systems:

- Understanding others (representation of psychological states and traits of others; empathy)
- Understanding oneself (visual self-recognition; recognition of own body and movements; self-reflection on present and past experiences; self-concept)
- Self-regulation (impulse control; reappraisal of emotional events; expressing feelings with words; unintentional self-regulation in placebo effect)
- Self-other interface (imitation; understanding oneself by referring to one's theory of others' minds; implicit and explicit attitudes; regulating prejudice and attitude change; social connection and rejection; social and moral reasoning; fairness and trust)

In this view, social cognitive processes do not include some lower-level processes mentioned by other theorist (e.g., social attention) but include executive functions (behavioral control and decision-making), which are typically excluded from the concept of social cognition. In sum, both psychological and neuroscience approaches are very diverse in their understanding of what social cognition is about. Currently, achieving consensus on the nature and structure of social cognition remains to be an unresolved task.

There are two other issues discussed by researchers and necessary for our understanding of the mechanisms and structure of social cognition. These issues are the relations between:

- Domain-specific and domain-general aspects of social cognition
- Automatic and controlled mechanisms of social cognition (Happé et al. 2017).

Both issues are directly related to the discussions on the nature and evolution of social cognition. The first question is whether social cognition

is based on general or specialized processes – the question directly related to the debate between general- and specialized-intelligence hypotheses. The current state of knowledge gives no univocal answer to the question. The studies in social cognitive neuroscience provide evidence that at least some elements of social cognition are based on highly specialized neural systems or mechanisms. Examples include the mirror neurons (action and emotion recognition), temporoparietal junction (theory of mind), fusiform face area (sensitivity to faces), etc. At the same time, methodological constraints of contemporary neuroscience do not allow to evaluate the degree of putative specialization of such systems.

The answer to the second question seems to be more definite. A wide range of the so-called dual process (dual systems) theories arguably differentiate between the two types of cognitive processes equally important for social cognition (Lieberman 2007; Evans 2008; De Neys 2018). The first system (system 1) is fast, automatic, implicit, and mandatory whereas the second (system 2) is slow, controlled, explicit, nonmandatory and of limited capacity. The interaction between the two systems can be found in many domains of social cognition including mentalizing, social perception, social categorization, although the mechanisms of such interaction can be more complex than previously suggested (De Neys 2018).

An example of the two systems interaction is the time-course of perception of the different types of social stimuli. In an experiment by Cunningham et al. (2004) White participants observed Black and White faces for two time periods corresponding to subconscious (30 ms) and conscious (525 ms) cognition. The amygdala, a part of the neural System 1, was activated more to the Black faces in the first condition whereas in the second condition (525 ms), its activity was reduced and the frontal cortical regions, responsible for the controlled processes, became active instead. This proves that both types of processes are involved in social perception and interact. A more complex and non-trivial example is the study by Freeman et al. (2010). They investigated how the brain responds to a set of faces, which were artificially transformed to represent a

continuity of sexually dimorphic faces, ranging from masculine to feminine. They found that whereas the fusiform gyrus, known to be responsible to visual perception of social stimuli, responded continually, depending to the degree of dimorphism, another brain area, orbitofrontal cortex, responded to faces in a discrete manner, encoding them as either males or females. These and other findings support the view that the dual process view on social cognition is useful, although the exact nature of the two systems functioning and interaction is yet to be studied.

Conclusion

There are no doubts that living in a complex social world requires multiple and advanced social cognitive abilities necessary to accurately represent this complexity, build short- and long-term relationships and determine appropriate behavior in various contexts. Although there is a general agreement that human social cognitive abilities evolved altogether with the evolution of sociality itself, the role of different factors and especially the balance between competition and cooperation remains debatable. The range and composition of phenomena described as social cognition by researchers remains equally diverse and often contradictory. Whereas some researchers focus on more basic, low-level social information processing, such as attention and visual perception of individual social agents, others pay more attention to higher-level constructs and operations, which include typologizations and abstract representation of the social world, strategic planning, and decision-making. Many of the more complicated aspects of social knowledge (e.g., ideologies, moral reasoning, strategies of self-identification) are normally discussed within philosophy, sociology, political studies, and other social sciences and remain beyond the studies in social and especially evolutionary psychology.

Key issues in contemporary studies include identification of specific neural systems and processes responsible for various aspects and types of social cognition as well as their interrelations and interactions. There are good reasons to think that

at least some social abilities are supported by specialized, domain-specific systems, although the degree of their specialization and contribution to complex, especially explicit social cognition remains a matter of discussions. Another increasingly important line of research is the studies of culturally conditioned neural processing of social information. Studies in cultural neuroscience show that many key social cognitive processes such as self-other distinction, social attention, memory, mentalizing are processed differently in various cultures at the neural level (Oyserman et al. 2014; Han and Humphreys 2016). Further studies in this direction are a promising step in understanding the evolution of social cognition as reflecting the evolutionary pressures from the interrelated ecological and cultural contexts.

Definition

Social cognition: mental processes involved in the acquisition and interpretation of information about the social world; communication: exchange of information between at least two individuals, where acts achieve their ends indirectly.

Introduction

The study of our closest living relatives, chimpanzees and bonobos, has been of interest to humans for well over a century. Darwin recognized the apparent similarities in our expressions in his 1872 book “The Expression of Emotions in Man and Animals.” More systematic research on their social cognition and communication in captivity started in the early 1900s, before they were recognized as separate species, with Köhler’s studies of chimpanzee intelligence (Köhler 2018), and was extended to wild chimpanzee populations in the 1960s with Goodall’s work in Gombe (Goodall 1986) and wild bonobo populations in the 1970s with Kano’s work (Kano 1992). However, unlike the crop of long-term chimpanzee research sites taking off at the

same time, repeated civil wars and limited infrastructure in the Democratic Republic of Congo delayed the study of wild bonobo behavior for decades. Even today, there remain relatively few places, in the wild or captivity, where it is possible to study bonobo behavior. Besides, what is the point? Research on these highly social long-lived species taken decades, in chimpanzees, we already have a *closest living relative* to compare ourselves against. Do we really need another one? The answer is of course, yes, and for all their obvious and more subtle similarities, there are equally obvious and subtle differences between them that are only starting to become apparent.

Both species live in large social groups and need to be able to acquire, interpret, and act on information about social relationships, including kinship, alliances, and dominance. Growing up in a social environment offers a range of ways in which you can gain social information and other benefits from those around you, whether kin or non-kin. The opportunity to learn, for example, about your physical environment: where is food? What is food? How to access or process food? In social-living species, an individual’s socio-emotional development depends on the opportunity to interact with others and form stable relationships, with profound life-long negative repercussions following atypical early social loss or isolation.

Today, the behavioral plasticity found within the species and subspecies that make up the *Pan* genus challenges the now outdated distinctions made between the *violent* chimpanzee and the peaceful *hippy* bonobo. However, there remain important differences in their social relationships, including in dominance, tolerance, and female cohesion, all of which impact the socio-cognitive tool kit they employ in their day-to-day lives. Direct comparisons within *Pan* species allows us to better understand them as modern species, but an understanding of within species flexibility and between species distinctions are also important for a more grounded discussion of the socio-cognitive suite of abilities present in our common ancestor.

The Species

Chimpanzees (*Pan troglodytes*) and bonobos (*Pan paniscus*) belong to the genus *Pan*. Both equally proximate to us in their genealogy, our lineage diverged from the *Pan* lineage around 5–8 Mya; chimpanzees and bonobos diverged from one another around 1–2 Mya, after which chimpanzees split into several subspecies. Recent studies suggest that bonobos may have evolved from an ancestral *Pan* population that crossed the Congo River at a time of drought (Takemoto et al. 2017).

Today, chimpanzees are listed as an Endangered Species (IUCN 2018), but despite this status, they represent the most abundant and widespread of the nonhuman great apes, typically occupying primary and secondary forest, but also grassland and savanna woodland. In the wild, chimpanzees are found across equatorial Africa, with a discontinuous distribution from southern Senegal across the forested belt north of the Congo River to western Tanzania and into western Uganda. The four formally recognized subspecies – Western Chimpanzee (*Pan troglodytes verus*); Nigeria-Cameroon Chimpanzee (*P. t. ellioti*); Central Chimpanzee (*P. t. troglodytes*); and Eastern Chimpanzee (*P. t. schweinfurthii*) – occupy mutually exclusive geographical ranges (Fig 1). Morphological differences across the four subspecies are relatively minor but they show substantial diversity in behavior from tool use and hunting, to female cohesion and the use of lethal aggression. Although part of this diversity can be explained as the result of variation in local ecology, for example, in the availability of particular foods or tool materials, other striking social and cultural differences persist, even where there is little evidence for ecological or genetic variation (Whiten et al. 1999).

Bonobos (*Pan paniscus*, Bilia or Mokonbusu) are also listed as an Endangered Species (IUCN 2018). Previously named *pygmy* chimpanzees, they are slightly smaller and more gracile, and display less sexual dimorphism in maturity. In the wild, bonobos are confined to the primary

and secondary rainforests of the Democratic Republic of Congo (Fig. 1). Their geographical range extends from the Lualaba River in the east to the Kasai and Sankuru rivers in the south, and the Congo River in the north, which forms a biogeographical barrier separating them from chimpanzees. Bonobos occupy forest-savannah mosaics that include tropical forest, dry forest, swamp forest, savannah woodland, and marshy grassland. Like chimpanzees, bonobo populations have experienced significant decline over recent decades, mainly due to habitat loss and poaching for the commercial bushmeat trade. Bonobos have no recognized subspecies: the constraints of the riverine barriers limit the gene flow between populations, which appear relatively stable. However, four strongholds have been identified: Maringa-Lopori-Wamba in the northern block (Lue Scientific Reserve, Lomako, Yokokala Faunal Reserve and Kokolopori Bonobo Reserve), Tshuapa-Lomami-Lualaba in the eastern block (Sankuru Natural Reserve), Salonga in the southern block (Salonga National Park), and Lac Tumba – Lac Mai Ndombe in the western block (Tumba-Lediima Natural Reserve) (Fig. 1).

Chimpanzees and bonobos are both diurnal and semiterrestrial. A large part of their typical activity budget includes foraging, feeding, and resting. Both species build sleeping nests in trees at night. Chimpanzee and bonobo females exhibit extended sexual swellings related to their estrous cycle, with a maximal swelling occurring near ovulation. While both species' maximal swelling is extended sufficiently to conceal the precise timing of ovulation, favoring a promiscuous mating strategy, this period lasts longer in bonobos and may lead to greater uncertainty about paternity (Boesch et al. 2002).

Chimpanzees and bonobos are omnivorous and opportunistic feeders. Their diet consists mainly of fruit supplemented with vegetation, seeds, roots, pith, and bark, but both species also eat honey, eggs, soil, resin, invertebrates, and vertebrates. Some of the variation found within and between species is likely driven by different necessities and opportunities related to the abundance of available food resources;

Social Cognition and Communication in Chimpanzees and Bonobos, Fig 1. Distribution of the genus *Pan*, including the four strongholds of bonobos and the four subspecies of chimpanzee. (Image credit Leonor Lavradio)

however, variation could also reflect individual selectivity. Chimpanzees, for example, are prolific hunters, with variation between even neighboring

communities in techniques and prey species. Both species hunt opportunistically and in groups. In chimpanzees, group hunting is more often

initiated by males, whereas in bonobos, females take a more active role and receive a larger share of meat (Boesch et al. 2002; Surbeck and Hohmann 2008). In contrast to bonobos, chimpanzees are skillful extractive foragers, frequently employing tools such as stones, sticks, and soft vegetation to extract and eat termites, ants, honey, nuts, and small mammals, again with cultural variation across populations and communities (e.g., Whiten et al. 1999).

Systematic research has been conducted with wild chimpanzees since the 1960s, focused at six long-term study sites each with over 30 years of continuous study: Gombe and Mahale in Tanzania, Sonso and Kanyawara in Uganda, Tai in Ivory Coast, and Bossou in Guinea. More recently, research has diversified, with at least 120 active field sites (Gruber and Clay 2016). Research in bonobos living in their natural habitat has been conducted in considerably fewer field sites. Long-term studies started in the 1970s in two field sites: Wamba and Lomako (Fig. 1), with Lui Kotale established in 2002. Research has been more regularly interrupted due to extended political instability and widespread epidemics, such as Ebola, but today, as in chimpanzees, the number of groups under study is starting to expand. As with wild populations, research opportunities in captive environments have also expanded, including both zoos and sanctuaries around the world, but in particular within an increasing number of semi-free-ranging sanctuaries in Africa.

Social Development and Behavior

Chimpanzees and bonobos live in multimale-multifemale fission-fusion societies, forming dynamic subgroups during the day (Goodall 1986; Kano 1992). They can live for over 50 years, with estimated generation times of around 25 years in both species. In some aspects, bonobos' social and physical development occurs more slowly than in chimpanzees with some apparently *juvenile* characteristics preserved into adulthood, such as high levels of play and non-conceptive sexual behavior, increased tolerance,

and decreased aggression. In other aspects, such as sexual development, time of emigration, and first reproduction, bonobos are more precocious. In chimpanzees and bonobos, males are the philopatric sex, remaining in their natal community, whereas females typically migrate to other groups when reaching maturity: at around 11–13 years in chimpanzees and 6–10 in bonobos (Gruber and Clay 2016). However, in chimpanzees, all mature males typically outrank all mature females and express a typically linear hierarchy, particularly among the highest ranked individuals, although the relative *steepness* or apparently despotic as opposed to egalitarian nature of these male hierarchies can vary between communities (Kaburu and Newton-Fisher 2015). In contrast, the highest ranked individuals in bonobo communities are typically mature females, and the overall pattern is more flexible, with some males having similar or higher ranks than some mature females (Boesch et al. 2002).

Chimpanzees are territorial and compete aggressively, at times lethally, over territorial space. In contrast, bonobos occupy more flexible *territories* in which there can be large overlap in areas of use between adjacent communities and positive intergroup encounters that may last for days. Chimpanzee males are highly gregarious and tend to establish strong bonds with other males, with whom they often share food, cooperate in shared activities such as boundary patrols, and support each other in social conflicts (Goodall 1986). Male bonobos do not typically form strong non-kin alliances or offer regular support to other males in agonistic contexts. Here, females are the more gregarious sex, and male sociability is more typically characterized by stable bonds with their mothers and other females in their communities (Kano 1992). Nevertheless, despite these broad-stroke differences in typical species behavior, there is striking variation within species, even in fundamental aspects of social behavior. For example, West African chimpanzees show low levels of lethal aggression and high levels of female gregariousness more reminiscent of bonobo communities than of their closer phylogenetic relatives, East African chimpanzees (Gruber and Clay 2016).

Social Cognition

Cooperation

Cooperation among relatives conveys benefits for individual fitness. Therefore, in philopatric species, such as chimpanzees and bonobos, more cooperation is expected among males. While bonobos are typically thought of as more *cooperative*, male chimpanzees cooperate across diverse contexts including high-risk high-cost behavior such as within-group coalitions, cooperative hunting, meat sharing, and territorial boundary patrolling. Both coalitionary behavior (two or more individuals cooperating to direct aggression toward others) and territorial boundary patrolling may result in severe injuries or even deaths within and between groups. In cooperative hunting, individuals may search for monkeys up to hours, time in which they may travel extended distances and forgo other opportunities to feed. These costs should be outweighed by the associated benefits, at least over individual lifetimes. So, for example, group hunting only appears to be stable in communities where the meat consumption per individual is higher than alternative individualistic hunting strategies. Males may also use meat sharing to strengthen their social bonds with other males or in a meat-for-sex exchange in females (Boesch et al. 2002). Similarly, despite lower levels of relatedness between females, in bonobos, it is females who primarily hunt for and share meat (Surbeck and Hohmann 2008).

Captive studies allow for more controlled exploration of the different factors that lead to cooperation. Both chimpanzees and bonobos work with conspecifics to solve cooperative tasks and show an understanding of the role that their partner's play in achieving them. However, differences in the social structure of both species may impact the ways in which they cooperate. In experimental settings, bonobos outperformed chimpanzees in cooperative tasks to achieve food rewards. One hypothesis argues that bonobos evolved in an environment with abundant resources and consequently with reduced feeding competition, leading to greater social tolerance than in chimpanzees (Hare et al. 2012). Similarly,

differences in ecology and demography may explain some variation found across communities within species, suggesting species differences may be more of degree than kind, and that caution should be used when extrapolating from any single population, particularly from captive ones given their unique socio-ecological environment.

Theory of Mind

Having a *theory of mind* (ToM) refers to the ability to assign mental states to other individuals (Premack and Woodruff 1978) and was long believed to be unique to humans. In human children, it is typically thought to be fully developed by around 4 years old but implicit understanding may be present from a much younger age (Schmelz and Call 2018). The cognitive capacity to understand others' mental states may be adaptive for many social-living species, as it may help them to predict others' behaviors, and over recent decades, ToM research has been extended to other primates and other animals (see Krupenye and Call 2019 for a review). Much of this work has focused on individual's ability to identify others' goals and intentions, and to understand others' perception and knowledge, including, for example, subjective desires and false beliefs (Krupenye et al. 2016). A significant challenge to investigating ToM is that most methods for doing so require at least some language use, providing challenges to our ability to explore the capacity not only in preverbal children but also in other species. As a result, it was unclear for many years to what extent the capacity to understand that other individuals have their own mental states was exclusively human, or whether its absence in other species was a reflection of our inability to detect it.

A major breakthrough in this field was the use of methods that take into account the socio-ecological perspective of the species being tested. In their 2000 study, Hare et al. asked "Do chimpanzees know what others do and do not see?" While not a direct investigation of ToM, understanding another's visual perspective is likely a key precursor to understanding another's state of mind. Crucially, rather than the many

cooperative paradigms used in the past, which require two individuals to work together to achieve a food reward, this study took into account chimpanzees' typically competitive approach to food and measured their abilities in an ecologically relevant paradigm. In doing so, they provided both the first consistent body of evidence for this capacity and, perhaps more importantly, a methodology that allowed the next generation of research to move forward in exploring other species' understanding of each other's minds. Over the past two decades, a body of work has built up supporting the existence of ToM in other ape species. Chimpanzees and bonobos seem to be able to interpret others' actions as goal directed and have a basic understanding of what others know and perceive. Experimental studies conducted in captivity and in the wild have shown that chimpanzees were able to distinguish between knowledgeable and ignorant individuals. Moreover, some experimental studies have shown that chimpanzees can reason about others' intentions, distinguishing situations such as: unwillingness to share from inability to share food; actions done on purpose or by accident; or a food thief from an innocent receiver of stolen food (Schmelz and Call 2018).

However, it remains unclear to what extent chimpanzees and bonobos are able to hold, and attribute to others, shared goals and intentions. Understanding *false belief* is the ability to understand that another individual may hold a belief that differs from reality. In the classic test of this capacity, a child watches while puppets place a chocolate in a cupboard, and then – when one of them is out of the room – the other moves the chocolate (Wimmer and Perner 1983). Being able to tell that, despite they themselves knowing the *true* location, that the puppet who was out of the room still believes it to be in the original (now *false*) location, shows the capacity to recognize that others' perspectives may differ from your own. Recent evidence using modern eye-tracking methods suggests that apes may be sensitive not just to others' knowledge but also to their, potentially *false beliefs* (Krupenye et al. 2016).

Recent work investigating ToM in chimpanzees and bonobos is not without critique. Non-mentalistic hypotheses can also be invoked to explain behaviors argued to represent evidence for theory of mind: for example, abilities such as self-recognition, deception, and perspective-taking can be explained by other processes like associative learning or even inferences about observable features of the situation rather than mental states. In false-beliefs tasks, successful performances could be also explained if subjects had learned heuristic rules of thumb “agents tend to search for things where they last saw them,” or that “the agent may found the object without fully representing that the actor believed that the object was in that location” (Krupenye and Call 2019; Schmelz and Call 2018).

To date, while there are still critiques to address, the trend of support is for increasing diverse evidence in favor of chimpanzee and bonobo's capacity to attribute psychological states to others and to understand others' perception, knowledge, and goals. These abilities are still less explored in bonobos than in chimpanzees, and there are hints they may differ in interesting ways; for example, bonobos appear to be less willing to cooperate when food, as opposed to food and social contact, is the only reward (Tan and Hare 2013). A more nuanced understanding of the differences between these two species requires not only testing the two species under similar conditions but also diversifying testing approaches so that they take into account the ways in which bonobo ToM may be expressed.

Social Learning and Culture

Where physical environments offer different problems and opportunities, differences in population behavior may result from adaptation to local ecology. However, population-specific behavioral traditions, in the absence of genetic or ecological variation, are an indication of potential cultural variation (Whiten et al. 1999). Comparing apparently cultural behavior in chimpanzees and bonobos provides fewer examples of cultural traditions in bonobos; however, as long-term research is needed to detect often subtle variation,

the more limited range of sites and the fewer cumulative years of study available impacts our ability to confidently describe the expression of bonobo cultural behavior (Hohmann and Fruth 2003).

Of the 65 behavioral patterns that Whiten and colleagues listed as candidates for cultural behaviors in chimpanzees in 1999, 14 were described in review of bonobo behavior (Hohmann and Fruth 2003); and others are regularly being added as research expands (Furuichi et al. 2015). The hand clasp is one example of a shared behavioral pattern across both species that appears to then vary in its use between populations within species. Here, two individuals sit facing one another, raise an arm, and clasp each other's hand overhead while engaging in mutual grooming. East African chimpanzees often engage in this behavior at Mahale but not in Gombe, and hand clasping occurs in some western chimpanzees' sites such as at Tai, but not in others, such as Bossou. Hand-clasp grooming has been described for some bonobo populations, such as Lomako (Hohmann and Fruth 2003).

A particular source of apparent divergence in chimpanzee and bonobo cultural behavior is in extractive-foraging techniques. Chimpanzees employ a wide range of diverse tools, from sticks, and stones, to leaves and moss to extract food from a wide range of sources, with extensive study of group-specific cultural differences. In contrast, in bonobos, only leaf- and moss-sponge tools for drinking water have been described to date (Hohmann and Fruth 2003). At present, the definitions and criteria imposed by the current methods to detect cultural behaviors in nonhuman animals are far more restrictive than the ones established for humans and, as a result, the size of the cultural repertoire of other species, particularly with regards to nonmaterial culture, may be being significantly underestimated. Schuppli and van Schaik (2019) have proposed a new method taking into account cultural adaptations to local ecological contexts, and even cultural universals. Developing the current methodologies used to study social learning may allow us to detect more candidates for cultural behavior in the future.

Communication

Gestures

Chimpanzees and bonobos use gestures in a flexible and intentional way to achieve a social goal (Graham et al. 2018; Hobaiter and Byrne 2011). At its simplest, in intentional communication, rather than broadcast a stimulus-driven signal, the signaler must choose to deploy a signal with the aim of changing the behavior of a specific recipient. While we have no direct access to the signaler's cognitive processes, we can employ reliable behavioral cues adapted from the study of intentional communication in preverbal human infants; for example, selecting the modality of signal appropriate for the recipient's visual attention, waiting for the recipient to respond, or persisting and elaborating based on the recipient's behavior. While the majority of the gestures are used to get help from another individual in attaining a physical goal, there is some evidence from studies of captive and wild apes that they may be able to express additional linguistic features such as reference (Liebal et al. 2014).

The gestural repertoires of bonobos and chimpanzees are large, containing over 80 distinct signals, but overlap almost entirely between the two species. Usually these repertoires are described in terms of their physical features, which may include the body part involved and the type of the movement (e.g., *arm raise*, *leg swing*), and are then grouped according to sensory modalities involved in perceiving the signal: silent gestures – those that create no sound or physical contact when made (also referred to as visual gestures, although all gestures contain visual information); contact gestures – those that include physical contact between the social partners (sometimes also referred to as tactile gestures); and audible gestures – those in which the production of the gesture necessarily includes an audible component. Ape signalers take the ability of the recipient to receive visual information into account when selecting from within their large repertoires, for example, using silent gestures when in full-sight, and contact or audible gestures when out-of-sight of the recipient (Hobaiter and Byrne 2011; Liebal et al. 2014).

Differences between chimpanzees and bonobos in their use of gesture appear to be related to species-specific differences in their sociality. Bonobos seem to gaze more frequently before they start signaling, and they are very proactive – often responding before the signaler finishes their communication. Chimpanzees adjust their body orientation toward recipients and engage in more time-consuming communicative negotiations that may involve longer periods of response-waiting and gestural sequences (Fröhlich et al. 2016). The gestures reported for bonobos that are apparently absent or rare in chimpanzees are typically used in sexual contexts, whereas those reported only for chimpanzees are more often related with male displays and dominance. Gestures are flexible and the same gesture can be employed to achieve multiple goals or multiple gestures used towards the same goal. Bonobo gestures appear to be more tightly associated with just one or two meanings, while there is greater flexibility in a larger proportion of the chimpanzee repertoire (Graham et al. 2018). Nevertheless, the description of gestural repertoires takes truly large datasets; group differences described in early studies were likely the result of under-sampling and, until more data are available on bonobos or a greater range of chimpanzee populations, apparent differences (or similarities) should be treated with caution. For example, variation in the frequency with which the two species engage in sexual and competitive behavior may create fewer opportunities to observe specific gesture types, which may be present in the species-repertoire but rarely employed (Graham et al. 2018). Bonobos employ tactile gestures more frequently, perhaps as a result of the higher degree of social tolerance and lower rates of physical aggression. However, to date, there has been little direct comparison of the two species within a single study method, and only wider and consistent data collection across communities, species, and subspecies will allow us to better understand their variability.

While the onset of bonobos' socio-cognitive abilities is typically a little later than their onset in chimpanzees; both species start using gestures to communicate at approximately the same time (Schneider et al. 2012). Around 9–10 months,

they begin using gestures in interactions with their mothers, with silent and contact gestures emerging earlier than audible ones. As they start to interact with other members of the group, both species tend to use fewer contact and more silent gestures (Schneider et al. 2012). How apes acquire their gestures is still debated. Striking similarities found within and between groups of the same species and even across different species of apes suggests that the available repertoires of signal types may be genetically determined and potentially present in *Pan* or even Hominidae common ancestors (Hobaiter and Byrne 2011). However, other mechanisms such as individual and social learning may play a role in the acquisition of some specific gestures; for example, conventionalization or ontogenetic ritualization (Tomasello and Call 1997), or social negotiation (Pika and Fröhlich 2019), and even where gestures are acquired as part of a biological repertoire, how they are used in day-to-day interactions is likely learned and adapted to the behavior of their social partners (Bard and Leavens 2014).

Vocalizations

Early studies suggested that vocalizations were tightly associated with emotional states and involved a lower degree of voluntary control in their production. However, more recent research suggests a higher degree of flexibility in the way that the signal can be produced and perceived. Both species seem to be able to modify their production of vocalizations in response to the presence of particular others, for example, close social partners or high-ranking individuals, and in a variety of contexts, in ways that suggest a degree of voluntary control (Liebal et al. 2014).

The vocal repertoire of chimpanzees and bonobos contains around 15 broad signal types and includes signals that sound alike in both species and that are used in similar social contexts, such as *panting-laugh* or the *pout moan* (e.g., Bermejo and Omedes 1999; Crockford and Boesch 2005). Nevertheless, the general acoustic structure of the two species' repertoire is dramatically different, with particularly significant variation in pitch (De Waal 1988). Variants of the same type of

vocalizations such as *grunts*, *screams*, *hoots*, and *barks* are used in both species but sometimes differ in duration, rhythm, or other acoustic features. For example, the *greeting grunt* in bonobos serves a similar function as the *pant-grunt* in chimpanzees but has a slower rhythm and lacks emphasis on the in-breath. Vocal repertoires also include species-specific vocalizations such as *hoos* in chimpanzees and *peeps* in bonobos. Both apes can combine discrete calls to form longer vocal sequences and combine vocalizations with other type of signals such as gestures and facial expressions (Bermejo and Omedes 1999; Crockford and Boesch 2005).

A particular challenge in describing both species' calls and *repertoires* is that their vocal signals are highly graded, with many sub-types and significant ambiguity between them. This ambiguity may allow social information to be transmitted through nuanced changes in acoustic structure. For example, information on the caller identity, age, social status, and their behavioral context, is encoded in chimpanzee calls such as *pant-hoots*, *screams*, and *whimpers* (e.g., Fedurek et al. 2016). Chimpanzees also encode information about perceived food quality through variation in a single call spectrum (*food grunts*). In contrast, bonobos produce sequences of different vocalizations such as *barks*, *peeps*, *peep-yelps*, *yelps*, and *grunts*, when interacting with food, and information about food quality appears to be encoded in the overall structure, although the specific patterns of association remain unclear (Clay and Zuberbühler 2009).

There is increasing evidence for flexibility in both chimpanzee and bonobo vocal production. Where two groups were combined in captivity, immigrant chimpanzees appeared to accommodate the structure of their food calls to match those of the resident chimpanzees. Both bonobos and chimpanzees appear to adjust the structure of their long-distance calls to match those of calling partners within their community. The ability to converge on some acoustic properties of group members' calls suggests the potential for group-specific *dialects*, where parallel convergence in

different groups occurs in different directions. For example, in West African chimpanzees, there is some evidence that the acoustic structure of long-distance *pant-hoots* from chimpanzees in the same forest varies so that groups that neighbor each other's territory are more acoustically distinct than groups who are further apart (Crockford et al. 2004).

Facial Expressions

Facial expressions convey abundant and diverse information about individual motivations and emotions and play a crucial role in coordinating social interactions. Facial expressions are tightly connected with the expression of emotional states – the presence of emotions such as fear, pleasure, distress, or excitement are typically seen as a necessary implicit component when defining facial expressions – and there remains significant debate about whether they are under voluntary control.

The facial musculature of humans, chimpanzees, and bonobos are very similar, but it does not follow that the same combination of physical components represents the same affective state. A standardized coding system based on muscle movements was developed for humans (The Facial Action Coding System: FACS) and later adapted for chimpanzees (The ChimpFACS) and other primates (e.g., MaqFACS, GibbonFACS, and OrangFACS). These Facial Action Coding Systems identify the minimal units of facial movement, referred to as *Action Units*, with each *expression* consisting of a unique combination of action units. Fifteen *Action Units* making up 9 facial expressions were identified for chimpanzees including: *bared-teeth display*, *relaxed open-mouth face* (also known as *play face*), *pant-hoot*, *scream*, *alert face*, *pout*, *whimper*, *neutral*, and an *ambiguous* category used for the facial expressions that could not be easily classified (Parr et al. 2007).

Higher high levels of face-to-face interaction and eye contact in bonobos has been used to argue that they may prioritize facial signals; however, their repertoire of facial expressions matches

those found in chimpanzees; although they show differences in duration, intensity, and how often they are used. During play, chimpanzees are more likely to use the partial form of the *relaxed open mouth*, while bonobos are more likely to use the full form, with both upper and lower teeth exposed. The chimpanzee *pout* is morphologically similar to the bonobo *silent pout*, but while the chimpanzee *pout* is associated with frustration after a rejection, the bonobo *silent pout* occurs in relaxed grooming sessions (De Waal 1988).

Conclusion

The last common ancestor of humans and *Pan*, and of chimpanzees and bonobos likely lived in large social groups, with a fission-fusion hierarchical social system. Different ecological challenges after the divergence of chimpanzees and bonobos may have dictated distinct social dynamics that favored the development of specific socio-cognitive skills in each species, but both species retain substantial flexibility and the differences expressed remain sensitive to population- and community-specific socio-ecological niches. Studying a large number of groups is important to describe the diversity within a species in order to avoid misleading generalizations of certain traits, abilities, or behaviors present in a subset being attributed to the whole species. While current models of human evolution are frequently based on a limited number of chimpanzee groups, the research landscape is diversifying allowing us to better describe both modern bonobo and chimpanzee species behavior, and more accurately describe the evolutionary trajectory along both the *Pan* and *Homo* lineages.

Definition

The evolutionary perspective argues that social comparison facilitated us in assessing our abilities and competition.

Introduction

Comparing oneself with others is central to the social life of humans and it is a particularly complex phenomenon. While engaging in social comparison can lead to positive outcomes, such as increased levels of hope and inspiration (Wood 1989), enhanced subjective well-being (Wills 1981), and a more positive self-view (Collins 2000), it can also result in dissatisfaction (Emmons and Diener 1985) and feelings of deprivation (Crosby 1976; Smith et al. 2012; Callan et al. 2015). Given the mass of information people are exposed to in modern societies, social comparisons occur more spontaneously than ever before. The wealth of social information afforded by technology, the Internet, and most evidently, social media, have amplified the frequency and intensity at which social comparisons occur. This holds important implications for the self-evaluations and well-being of people in modern times.

This entry reviews the social comparison theory from an evolutionary perspective, highlighting *why* humans engage in social comparison despite potentially experiencing negative feelings when comparing themselves to others. In doing so, this entry also demonstrates how social media interacts with our evolved psychology to result in

excessive social comparisons, which in turn brings about the various effects on behaviors and well-being that is observed today.

Theory of Social Comparison

Social comparison theory posits that as humans, we compare ourselves to others as we have an innate desire to evaluate our opinions and abilities (Festinger 1954). In doing so, we derive at various outcomes, including having an accurate self-portrayal (Festinger 1954), aspirations to improve our skills or abilities (Wood 1989), and protecting or enhancing our self-esteem (Wills 1981; Wood 1989; Tesser et al. 2000).

The process of social comparison can be grouped into two broad categories: upward social comparison and downward social comparison. Upward social comparison occurs when we compare ourselves to others who are better than us in certain aspects. Typically, upward comparison provides aspirations and motivations which elicit behaviors aimed at improving oneself to be more like the standard of the comparison target (Wheeler 1966; Thornton and Arrowood 1966; Taylor and Lobel 1989). However, upwards social comparison also brings about lowered self-esteem (Wheeler and Miyake 1992), worsened mood states (Gibbons 1986), feelings of deprivation (Crosby 1976; Smith et al. 2012; Callan et al. 2015), and dissatisfaction (Emmons and Diener 1985).

In contrast, downward social comparison occurs when we compare ourselves to others who are less fortunate or worse-off than us. Downward comparison is usually employed when one seeks to protect or enhance self-esteem as such comparisons result in enhanced mood and more positive evaluations of the self (Wills 1981; Pyszczynski et al. 1985). While there exists different motivational states for each type of social comparison (Brown 1991; Sedikides 1993; Collins 1996), and moderators which would influence the outcomes of each type of social comparison (Collins 1996), such as self-esteem (Wheeler and Miyake 1992), group identity (Major et al. 1993), and closeness of comparison target

(Brewer and Weber 1994), these discussions is not within the scope of this entry. Instead, the focus on this entry centers itself on the evolutionary perspective of the social comparison process.

Social Comparison – An Evolutionary Perspective

Human psychology and behaviors are the products of our evolved psychological mechanisms, which are adaptations that has resulted from successfully overcoming obstacles that threaten survival and reproduction. Both the need to survive and the need to reproduce are adaptive problems, and humans have evolved a range of psychological mechanisms over the course of evolutionary history designed to optimize solutions to these problems. For example, to survive, one would need to form alliances with others and defend against enemies. The operation of psychological mechanisms that function to identify parties to form alliances with results in cooperative behaviors that initiate the forming of an alliance. Similarly, to achieve reproduce success, one would have to acquire reproductively viable mates; psychological mechanisms function to identify and pursue mates with high quality reproductive traits in order to increase reproductive success. Psychological mechanisms engage adaptive behaviors that serve to increase the chances of survival and reproductive success. Social comparison is a psychological mechanism that inhibits or facilitates subsequent behaviors.

From an evolutionary perspective, social comparison served several functions that aided in survival and reproductive success. Comparing oneself with others allowed for humans to determine the social ranking of themselves relative to others (Gilbert and Allan 1994). Individuals who were higher in the social hierarchy make better allies as they tend to have more resources and breeding opportunities than those who were lower in the social hierarchy. As such, when one recognizes themselves to be lower in the social hierarchy, they behave in ways that signal that they are not in an aggressive state of mind and are not seeking any challenge. Such submissive behaviors will not be evident in individuals who identify themselves to be higher in the social

hierarchy, who were more likely to exhibit assertive displays (Gilbert and Allan 1994).

Social comparison also afforded the assessment of competition, which was vital for out-competing others who are after the same pool of resources (Trivers 1985). This judgment of relative probabilities of success decides subsequent behavior and is best evidenced in the mating context.

Social Comparison in Mating

To ensure reproductive success, one must, first, possess traits preferred by the opposite sex, and two, ensure that the traits they possess are better than others who are also competing for the same pool of mates. Social comparison facilitates this process as it allowed one to identify the qualities that are deemed attractive by the opposite sex and recognize one's standing in the mating competition. Men and women evolved to prefer different traits in their mates due to the different adaptive problems they have faced in the ancestral past. As men's reproduction is constrained by the declining fertility of women, men tend to prefer traits that signal high reproductive value in women such as physical attractiveness (Buss 1989) and a low waist-to-hip ratio (Buss and Schmitt 1993). In contrast, women required protection and resources for her and her offspring, and as a result, women evolved to prefer men with social status as this was ancestrally an indicator of physical strength and is related to their ability to provide resources (Buss 1989; Buss and Schmitt 1993). Because these key traits are sort after by other same-sex individuals, knowing one's relative standing in the competition enable them to direct effort to obtain favorable attention (Gilbert et al. 1995), such as improving on the quality of these key traits, should they fall short.

Even though competition for mates is more evident among men as a result of their ability to achieve greater reproductive success with increased mating events (Darwin 1871), women also participate in this competition for mates – especially when there are more women than men (Stone et al. 2007). In current times, social media and its reach of over a million users has induced the social comparison process excessively. Both

men and women now perceive that they are competing for mates against an extremely large pool of competitors. Additionally, dense human populations (Sng et al. 2017) consisting of different ethnic groups (Kanazawa and Li 2015) in modern environments obstruct the effective operation of social comparisons. As a result, maladaptive consequences are now commonly associated with social comparisons.

Social Comparison in the Modern World

Evolutionary Mismatch

The modern environment, characteristically consisting of technological gadgets and cosmopolitan-ness, is quite different from the environment in which our psychological mechanisms have evolved. This results in a mismatch between the modern environment and our evolved psychological mechanisms (Li et al. 2018; Tooby and Cosmides 1990). The consequence of such mismatch is that psychological mechanisms that were adaptive in the ancestral environment are now producing maladaptive outcomes. One of the most commonly cited examples is our preference for sugary and fatty food; where such food provided superior nutrition and calories to humans in the Pleistocene environment where humans have evolved from (Barkow et al. 1992). However, now with most food producers manufacturing foods high in sugar and fat, and our evolved preference for such food type still in operation, this has resulted in obesity (Buss 1995). Such a framework allows us to understand how evolved psychological mechanisms that were once adaptive produce maladaptive outcomes in modern contexts.

Social Media and Modern Societies

Social media, broadly referred to as platforms allowing for the production and sharing of content online including social networking sites and weblogs, is an integral part of everyday life in our modern societies. Social media has afforded us many opportunities for forming new social bonds and maintaining existing ones (Boyd and Ellison 2007; Manago et al. 2012). One

characteristic of social media is that it allows users to create their personal profiles, and thereby, present information about themselves. More often than not, users present themselves in positively on their profiles by including self-promotional and socially desirable contents, such as their accomplishments and possession of consumer goods (Zhao et al. 2008; Mehdizadeh 2010; Rosenberg and Egbert 2011; Nadkarni and Hofmann 2012). Social media users spend a lot of time on social media browsing profiles more so than engaging in interactions with others (Joinson 2008; Pempek et al. 2009). The consequence of such online behaviors typically triggers social comparisons, especially when they view posts and photos of others (Lee 2014). Since most profiles reflect the best aspects of users' lives, most users end up comparing themselves to those who are perceived to be better than them (Chou and Edge 2012; Feinstein et al. 2013).

Upward social comparison leads to positive feelings about the self, but this usually happens when one subjects themselves to it by choice (Nosanchuk and Erickson 1985; Collins 1996). With the massive amount social information users are constantly bombarded with on social media, users would be forced to engage in upward social comparisons. Moreover, with digital and physical enhancements, the competition users face also "possess" traits of levels that are surpassingly high, leading them to perceive that there is hardly a way to out-compete others. Such chronic comparisons have been associated with maladaptive outcomes, including depression (Feinstein et al. 2013), self-esteem declines (Kalpidou et al. 2011; Lee 2014; Vogel et al. 2014; Gonzales and Hancock 2011), negative self-evaluations (Haferkamp and Krämer 2011), and lower levels of well-being (Kross et al. 2013).

Finally, modern societies usually consist of multiethnic individuals (Kanazawa and Li 2015). Living with people of different ethnicity is unheard of in ancestral times – humans lived in ethnically homogenous groups (Oppenheimer 2004). Hence, they are usually perceived as potential threats and the well-being of individuals living in such environments is usually low (Kanazawa and Li 2015; Li and Kanazawa

2016). More importantly, with individuals who look different, speak different, and endorse different values, it complicates how one selects the target of social comparison, which may subsequently lead to an unstable evaluation of the self (Festinger 1954).

Conclusion

We compare ourselves to others in order to derive an accurate evaluation of ourselves, to make ourselves feel better, or to inspire us to become more like those we hold our comparisons too. While these strategies should generally serve to increase our well-being, the society we live in and our copious use of social media has made social comparisons unbearable. Modern environments, with populations consisting of different ethnicities, makes establishing a similar comparison target difficult. Moreover, with an explosion of social information where people tend to portray achievements and possessions that signal a high-quality life, we are subjected to an illusion where we perceive an overwhelming number of competitors that is impossible to out-compete. As a consequence, social comparisons bring about several undesirable outcomes including more negative evaluations of the self and lower levels of self-esteem and well-being.

Social Consequences of Initiating Gossip

Piper Harris
University of California, Santa Barbara, CA, USA
University of California – Los Angeles, Los Angeles, CA, USA

Synonyms

Benefits of gossip; Evaluative conversation; Implications of gossip; Negative effects of gossip; Talking about others

Definition

The social implications and effects of initiating evaluative conversation about a third party who is not present for the discussion.

Introduction

Gossip is defined as the sharing of evaluative information, either positive or negative, about others who are not present for the conversation

(Beersma and Van Kleef 2011, 2012; Farley 2011; Foster 2004). Gossip is heavily incorporated in humans' interactions and is estimated to comprise between 65% and 90% of people's everyday conversations (Beersma and Van Kleef 2012). Research has also demonstrated that even 4- and 5-year-old children engage in gossip as a means of learning about their environments (Baumeister et al. 2004). While gossip is often perceived as malicious, condemnable behavior (Beersma and Van Kleef 2012), evolutionary psychological research has demonstrated that there are numerous positive consequences that arise from initiating gossip, such as providing and gathering useful information, protecting a group from self-serving and free-riding behavior, strengthening bonds, and heightening one's social status (Baumeister et al. 2004; Beersma and Van Kleef 2011, 2012; Ben-Ze'ev 1994; Dunbar 2004; Enquist and Leimar 1993; Farley 2011; Foster 2004).

Providing and Gathering Information

Gossip is an efficient and effective way for people to share and receive information about the individuals/situations to which the gossip refers (Beersma and Van Kleef 2012; Ben-Ze'ev 1994; Foster 2004). Providing and gathering knowledge has consistently been identified as a significant reason that people engage in gossip with others (Beersma and Van Kleef 2012; Dunbar 2004). Instigating gossip about others' successes, as well as trials and tribulations, reveals potentially useful information to the receiver of the gossip to help them navigate and understand their environment. It is a powerful means of passing along practical information about the norms and standards of a culture or society that may not be learned otherwise (Baumeister et al. 2004; Ben-Ze'ev 1994). For example, a mother might tell her child a story about someone she knows who began using drugs and ultimately ruined their life in order to convey to her child the potentially lifesaving information that drugs are harmful and should be avoided. In this instance, commencing "gossip" in the form of storytelling about others

serves the purpose of teaching valuable lessons that may not be absorbed as effectively otherwise (Baumeister et al. 2004; Beersma and Van Kleef 2012).

Group Protection

Gossiping with others allows one to caution group members against those who deviate from group norms (“norm violators”) or take advantage of a group. When working in groups, it is common for some members to not contribute to the work but still receive the benefits – this is commonly referred to as “free-riding,” as such individuals share the success/benefits of the group work without actually assisting (Beersma and Van Kleef 2012). Gossip serves an important evolutionary function in protecting against such norm-violating behavior (Beersma and Van Kleef 2012; Enquist and Leimar 1993). Researchers Beersma and Van Kleef (2011) found that when participants in a study were told that the other group members would gossip about their participation, they contributed more to the group, consequently decreasing their free-riding and self-serving behavior. In this instance, initiating gossip functions to protect a group against those who wish to take advantage by enforcing the group’s norms and expectations and subsequently decreasing self-serving behaviors by members of the group (Beersma and Van Kleef 2011, 2012).

Strengthening Bonds

Initiating gossip can allow one to strengthen their relationship with the person whom they gossip (Foster 2004). Gossiping together allows the individuals participating to spend time together in the conversation, serving as a mechanism for social bonding (Baumeister et al. 2004; Dunbar 2004). Initiating gossip “communicates alliances, increases the intimacy of social bonds, and delineates the distinctions between the in-group and out-group” (Farley 2011). Furthermore, one who initiates gossip shares information that could be

useful or pertinent to the receiver, strengthening their social bond (Baumeister et al. 2004; Dunbar 2004).

Social Status

Gossip has the potential to increase or decrease one’s social status (Baumeister et al. 2004; Farley 2011). Research has found that those who instigate gossip may be seen as having an elevated social status because they are demonstrating that they comprehend social rules or regulations that may be unknown to or not understood by the receiver of the gossip. In other words, the individual who shares the gossip is perceived as having knowledge or understanding that is not possessed by the receiving party (Baumeister et al. 2004; Foster 2004). Furthermore, the instigator of gossip is perceived as having more social influence by being aware of their environment and changes within it and consequently sharing this information with others (Dunbar 2004; Farley 2011). However, engaging in too much gossip, or gossip that is negative about the target, can have undesirable effects. Farley (2011) found that people who engage in gossip frequently are perceived as less powerful and likeable compared to individuals who do not gossip as frequently. The same findings were true of those who gossip about others in a negative sense compared to in a positive regard (i.e., critiquing someone’s appearance versus complimenting it). Thus, this study revealed that individuals who engaged in high-frequency, negative gossip were perceived as being the least socially powerful and likeable compared to other types of gossipers (i.e., low-frequency, positive gossipers) (Farley 2011).

Gossip also has the potential to influence the social status of the target of such gossip. One who instigates gossip has the power to manipulate the target’s reputation by spreading information about that person. The gossipier has the potential to paint an influential, negative picture of the target, which can potentially induce social exclusion, a highly undesirable consequence for the target of the gossip (Beersma and Van Kleef 2011).

Conclusion

Research has demonstrated that gossip can have a number of positive, beneficial social consequences, such as a means of providing and gathering information about others, defending against self-serving behaviors within groups, fortifying relationships between individuals, increasing one's social status, or even decreasing the social status of someone else. However, too much gossip with a negative connotation can ultimately lead one to be portrayed as unlikeable and unpowerful. Initiating gossip can have undeniably advantageous consequences when one is mindful of the type of gossip they engage in and how often they do so.

Definitions

Social contexts, Microsystem, Mesosystem, Exosystem, Macrosystem, and Chronosystem.

Introduction

According to the APA (2018), social context refers to the situational circumstances or conditions that exist in the social environment of individuals. These circumstances, directly or indirectly, influence individuals' developmental outcomes, behaviors, thoughts, and feelings, as individuals spend an incredible amount of time, energy, and effort in interacting with the elements of social contexts (Bronfenbrenner 2009). These interactions can be both passive and active

(reciprocal) and the influences of the elements can be both direct and indirect, thereby making social context a dynamic environment.

Bronfenbrenner (2009) highlighted and expanded on the role of the social environment in his PPCT model of Bio-Ecological Theory. He suggested that the five systems, namely, *micro, meso, exo, macro, and chrono*, along with their elements, make up the environment (aka social context) of an individual. Bidirectional interactions and exchanges within and between systems and elements are known as *proximal processes*, and these *processes* contribute to the dynamic aspects of the environment. For example, the social context of a child “A” raised in a high SES with access to quality resources in a two-parent family is in contrast with a child “B” who is raised in a low SES, by a single-parent family and lives in a risky neighborhood. These proximal processes in *microsystem* and rippling effect of the outer systems such as strenuous work environment of the parent, lack of medical facilities, and resources in the community along with marginalizing and discriminatory practices based on race, class, sex, and gender can negatively influence the developmental trajectory of child “B.”

Although, understanding social contexts assists in predicting individual or group outcomes; the role of social context is not limited to precise conceptualization and examination of the developmental outcomes. In fact, a thorough examination of the social context guides the construction of best practices for research and interventions. Given below is a brief description of the implications of social context for individual outcomes, research practices, and interventions.

Implications for developmental outcomes.

Social/contextual factors, along with biological factors, dictate the cumulative effects on the momentum and direction of the developmental outcomes of an individual. Schriber and Guyer (2015) applied neurobiological susceptibility models to provide a rationale for the differential outcomes of interventions among adolescents. The researcher suggested that certain biological factors in the brain confer higher susceptibility to environmental influences, forging these

adolescents to be more responsive to interventions than their age mates. In addition to greater susceptibility to environmental influences, adolescents who experience warm and supportive environments have more significant gains in comparison to those who are neither context-sensitive and nor have a positive environment around them. Notably, the authors emphasized the role of sensitive periods and concluded that interdisciplinary lens is crucial to draw accurate conclusions regarding the effects of social context on developmental outcomes.

Implications for research and interventions.

Social context not only helps in understanding the complexity of the social issue in terms of the gravity of the situation, but it also identifies and clarifies the role of related moderators and mediators that must be accounted for while analyzing data and deciding appropriate levels for prevention and intervention programs (Glisson and Schoenwald 2005). To illustrate, Alegria et al. (2019) conducted longitudinal research to study the impact of having a “minority status” on mental health outcomes of 1863 Puerto Rican and South Bronx youth. Overall, the research team concluded that higher perceptions of minority status are related to higher manifestations of anxiety and depressive disorders. However, mental outcomes were moderated by positive social relationships, and mental health outcomes were mediated by social stress related to discrimination, more so among South Bronx youth than Puerto Rican youth.

Based on the above-stated findings, most investigators would suggest interventions at the individual level for South Bronx youth; but Alegria et al. (2019) recommended interventions at the community level as in the presence of substantial community-level risk factors; individual-level support systems may eventually become ineffective. In comparison to Puerto Rican, South Bronx youth was characterized by a substantially higher number of single-parent families, violence, and perceptions of discrimination and unfair treatment. The South Bronx youth also reported a weaker ethnic identity and poor relationships with family and peers. Therefore, investigation of the social context of different outcomes and its interpretation in the light of research

findings are warranted. Only after assessing all the main, moderating, and mediating effects of social context, accurate conclusions for research findings and program components can be drawn (Glisson and Schoenwald 2005).

Social context also offers insights into the long-term impacts of prevention and intervention programs. To elaborate, Miklikowska et al. (2019) refuted the previous studies that suggested parent-based interventions to diminish prejudice against immigrants in Sweden. Previous findings were based on moderate-positive correlations between adolescents' and parents' prejudicial attitudes. Miklikowska et al., after investigating the social context of Swedish youth, suggested that even though pro-immigrant environment at home may diminish prejudicial attitudes among youth, yet the effects of the intervention will not be long-term without integrating peers' prejudicial attitudes in the equation. Positive contact with ethnically diverse peers may not only lower prejudice but may also cancel out the negative impact of anti-immigrant messages from parents.

Conclusion

To conclude, social contexts play a vital role in determining life course trajectories (Stokes 2018), and therefore the integration of social context in research and practice is warranted to understand human motivations that direct them to a specific direction or make them more amenable to change.

Social Contract Rule Violation

Daniel Farrelly

University of Worcester, Worcester, UK

[Cheater detection](#); [Social reasoning](#)

Definition

When an individual in a social exchange with another “cheats,” by taking a benefit without incurring a cost and/or returning the favor to another.

Introduction

One of the founding principles of Evolutionary Psychology is that the human mind consists

of domain-specific modules that have been shaped by evolution. This modular view of the mind suggests that our ancestors were able to use these modules to help solve specific problems they encountered in their environment. Possibly the most well-known example of such a module is one dedicated to reasoning about social contracts (Cosmides 1989; Cosmides and Tooby 1992). In such contracts, there will be a rule about how an individual is expected to behave (e.g., “if you take a benefit from another individual, then you must return the favor in some form”), and when entering such an exchange each individual is aware of this. According to Cosmides and Tooby (1992), individuals who violate such rules (i.e., “cheats” who take a benefit without incurring a cost or returning the favor) need to be avoided as partners in social contracts, as they will be exploitative and costly with no benefit. Therefore, a “cheater detection” module has evolved in humans which makes us very good at detecting and remembering individuals who cheat in social contracts.

Cosmides and Tooby (1992) provide evidence of this heightened ability to detect cheats in social contracts using the Wason Card Selection Task (Wason 1966). In the standard format of this game, individuals are presented with four cards lying down and are told that each card has a number on one side and a letter on the other. An example of the four cards can be seen in Fig. 1.

Individuals are then asked which cards they would need to turn over to see if the following rule is correct: “If there is an even number on one side, then there is a vowel on the other.” In this abstract version of the task, few people choose the correct options (the “4” and the “D” card), in fact only about 25% get it right.

However, this changes when the original abstract version of the task is replaced by one that features a social contract (Cosmides and Tooby 1992). For example, in the following version individuals were again presented with four cards but were now told that each card has a drink on one side and a person’s age on the other. An example of this social contract version of the task can be seen in Fig. 2.

Social Contract Rule Violation, Fig. 1 The abstract version of the Wason Selection task

Social Contract Rule Violation, Fig. 2 A social contract version of the Wason selection task

Individuals were told to imagine they were working in a bar and had to ensure that the following social contract was upheld: “If a person is drinking alcohol, then they must be twenty-one years old or older.” Compared to the abstract version of the task, a majority of people (approximately 90%) answered correctly (the “Beer” and the “18” card). So why such a difference in accuracy, if the underlying reasoning logic for the two tasks were the same? Cosmides and Tooby (1992) suggest that as the latter version involved a social contract, it activated individuals’ “cheater detection” module, meaning they were better able to spot cheaters here. In other words, drinking alcohol can be considered a social contract, where individuals must incur a cost (i.e., being twenty-one or older) in order to gain a benefit (i.e., drinking alcohol). Therefore, we are better able to identify violations of this rule, which is someone taking the benefit (drinking beer) without incurring the costs (being aged 18), and select those cards accordingly more readily.

Further evidence of the existence of heightened ability to detect social contract rule violation comes when novel or unusual social contracts are used. For example, Cosmides and Tooby (1992) also presented individuals with a similar card task but with a different social contract rule for them to check; “if you get married, you must have a tattoo on your forehead.” Even though this was novel for individuals (compared to the drinking alcohol/age

rule), accuracy here was still very high (approximately 75% picked the correct cards). Also, when tested cross culturally, it has been found that performance is similar, which suggests that an ability to detect social rule violators is universal. For example, Sugiyama et al. (2002) found that among the Shiwiar tribe in Ecuador, performance on the social contract versions of the selection (86% selected the correct cards) was very similar to that of the original US sample. This evidence highlights that it is not familiarity with a social contract rule that causes heightened detection of social rule violators but an underlying evolved ability humans have to recognize a social contract whether it is familiar or novel that allows us to detect cheats quickly and accurately.

Evidence also exists that reasoning relating to social contract rule violation is separate to that of similar cognitive abilities. For example, Stone et al. (2002) found that patients with brain damage performed normally on abstract versions of the Wason Selection task, but poorly on versions that involved social contracts. Also, due to the high costs involved in social contracts, the role of emotions in reasoning about social contracts has been shown to be important (Reis et al. 2007) and violations of social contracts elicit anger as the predominant emotion (Fiddick 2004). Finally, recent evidence exploring personality traits as predictors of social contract reasoning has shown that conscientiousness (and to a lesser extent trust) correlates with social contract reasoning abilities (Brase et al. 2019), further showing how human reasoning is affected by social contexts.

Conclusion

By showing that humans would have faced the problem of who to trust in social exchanges, and that we have evolved an ability to understand these social rules, researchers such as Cosmides and Tooby have shown how our cognition can be tuned to certain topics. These topics were relevant in our evolution, and our better reasoning with these than with more abstract topics suggests our minds are built for specific, not general problem-solving.

Definition

The application of Darwinian biology and evolutionary principles to human social theory.

Introduction

In the broadest sense, the term *social Darwinism* has been used to refer to any effort made toward applying concepts from Darwin's theory of evolution by natural selection to social theory, political systems, economics, and other domains of human social life (Dickens 2000). However, social Darwinism is likely best known for its infamous association with early twentieth century political ideologies targeted at "improving the human race." Darwin's ideas were used to justify eugenics (Nourse 2016), race war (Barondess 1998), imperialism (Leonard 2009), and a variety of economic political ideologies (Hawkins 1997). However, these ideas were often based on misinterpretations of Darwin's original ideas and the

process of natural selection. Some have argued that early academics who have since become associated with nefarious applications of social Darwinism (e.g., Herbert Spencer, William Graham Sumner, Richard Hofstadter) were often misinterpreted or misrepresented (Hodgson 2004; Leonard 2009). Moreover, earlier work did not incorporate many contemporary discoveries within evolutionary biology that have since replaced some of Darwin's original ideas (e.g., Fodor and Piatelli-Palmarini 2011).

Natural Selection

Perhaps one of the most widely misinterpreted concepts within the theory of evolution was the phrase "survival of the fittest." The lay understanding of this phrase (i.e., "the strongest individuals survive") has been the mantra for social and political policies aimed at favoring one group of individuals over another (e.g., Barondess 1998). However, this understanding of the phrase is inaccurate. In evolutionary biology, "survival of the fittest" is a catchy and succinct way of describing one of the central processes of evolution: natural selection. Natural selection occurs when variation in a heritable trait (e.g., intelligence) leads to differential reproduction within a population of individuals. For example, individuals who were relatively more intelligent may have been better at adapting to new situations, inventing creative solutions to novel problems, and attracting potential mates. Therefore, more intelligent individuals would have experienced greater reproductive success compared to less intelligent individuals. Over several generations, if intelligence consistently conferred this reproductive advantage, intelligent individuals would have begun to outnumber relatively less intelligent individuals in the population. In this example, the process of natural selection thereby leads to the survival (i.e., consistent and continued reproductive success) of the fittest (i.e., individuals who possess a trait which confers a reproductive advantage over competitors). Therefore, "fittest" does not necessarily equate to "strongest." In fact, some adaptations for physical strength could be

detrimental to an organism's reproductive success if, for example, diverting somatic resources to muscle development were to become an inefficient use of the body's resources.

Relatedly, there are no traits that are inherently better than other traits. A common justification for the use of eugenics (Nourse 2016) was that the human race could be improved by artificially selecting traits which were believed to be genetically superior (e.g., blonde hair and blue eyes). However, this presumes knowledge of which traits will confer a reproductive advantage. A trait only benefits an individual's reproductive success insofar as it helps the organism adapt to current environmental conditions. Returning to the example of strength, within environments where same-sex competition between males is intense, physical prowess may increase competitive success and thereby reproductive success. Likewise, physical strength might allow individuals to manipulate large objects or protect kin, friends, and mates. In this sense, one could argue that physical prowess should be artificially selected for inclusion in future human populations. However, having less physical strength may also increase reproductive success within particular environments. Greater physical strength typically entails more muscle mass and therefore greater body size, which may slow an individual down or make an organism conspicuous and more likely to be preyed upon. Genes coding for greater physical strength may also inadvertently affect the expression of other traits, such as circulating levels of testosterone and behavioral aggression. In this way, something that is typically seen as "better" (i.e., strength) may actually contribute negatively to an organism's overall fitness within a particular environment. This is only one example, but the basic logic may be applied to a variety of potential traits. Those who applied this logic to social and political theory were not concerned with reproductive success, *per se*, as much as with optimizing various aspects of human social, political, and economic systems (Dickens 2000; Hawkins 1997). However, applying evolutionary logic in this way is similarly flawed in these contexts. People, and social systems, are the products of multiple intersecting processes and traits.

Altering or favoring one trait (e.g., physical strength) without conscientious consideration of this change's impact on related attributes and processes (e.g., behavioral aggression) could have unintended consequences.

Contemporary Social Darwinism

Any version of social Darwinism which has had its origins in these flawed understandings of Darwinian and evolutionary logic has no credibility in current evolutionary science. Yet, some modern social and evolutionary theorists still discuss (and debate) how evolutionary principles might be applied to the study of human social systems (e.g., Dickens 2000; Hodgson and Knudsen 2010; Schubert 2012). This debate includes whether social evolution (i.e., memetic descent and modification) more closely resembles Lamarckian or Darwinian evolution (Hodgson 2001), whether welfare economics may be reformed using evolutionary principles (Schubert 2009), and how an understanding of psychological adaptations can inform various facets of human morality and politics (see Shackelford and Hansen 2016). Unlike its predecessors, contemporary social Darwinism adopts a more nuanced and morally conscientious approach to integrating human social behavior and evolution. Indeed, although social Darwinism has acquired a stigma within many intellectual circles, an understanding of how evolution has shaped human psychology will provide clues about how to optimize the various social, political, and economic systems that have emerged from that psychology.

Enculturation; Social habit development; Socialization; Unfolding; Upbringing

Definition

Children develop their sociality according to propensities for cooperation and from their family and community experiences. In precivilized societies, social development occurs naturally as children learn the ways of the community through informal apprenticeship. In civilized societies, social development often involves “socialization,” as adults coercively teach children how to behave.

Introduction

We can contrast two basic forms of societies: civilized and pre- or un-civilized. Civilization has been around for about 10,000 years (about 1% of human genus history). Civilized societies are those that domesticate and control the lives of animals and plants to their own benefit, hoarding resources and constructing hierarchies to keep the social system of controlling resources in place. Civilized nations have been successful technologically but destructive of earth life and biocultural systems as they expand to eliminate and cultivate more and more wilderness areas and land governed by others. They must also ensure their populations conform to the system. Thus, socialization and social development has this as a primary aim.

On the other hand, humanity spent about 95% of its history outside of civilization (Fry 2006). “Uncivilized” societies have continued alongside the civilized to the present day (Lee and Devore 1968). “Uncivilized” groups will be termed “primal” groups here because the social structure is ancient, and they are more in tune with ecological systems, upon whom they traditionally directly rely. The data accessed are mostly from small-band hunter-gatherer bands or nomadic foragers who are immediate-return societies (migratory, with few possessions, no cultivation of plants, no domestication of animals; Woodburn 1982). Because they migrate in particular landscapes according to the availability of food sources like other migratory animals do, primal societies are

careful not to over harvest plants or animals so that these will be available on their next visit to the locale. Social development takes a natural course in these societies, unfolding as the maturational schedule of the child dictates in relation to the pressures of living in the local landscape. The goal is to become a full human being who lives well and responsibly under the local conditions.

In this entry, distinctions are made between the societies that socialize for civilization and those that do not. The two approaches to social development are contrasted in the sections below.

Humanity's Inheritances

Although genes are often the focus of human inheritances, humanity inherits much more, including for example, landscape ecology, cultural practices, maternal microecology, and capacities for self-organization (Kauffman 1993; Oyama et al. 2001). Humans also inherit greater epigenetic plasticity, especially in early life, than other apes (Gómez-Robles et al. 2015).

As all animals do, humans have a nest that evolved to optimize the development of the young. The nest represents “the reliable and repeatable features of stimulation and experience occurring in an organism’s developmental context” (Lickliter and Harshaw 2010, p. 497), a species-typical developmental system that leads to a species-typical outcome. For humans, who are part of the social mammalian line, the early life nest is provided by the mother and her community and includes soothing perinatal experience; nearly constant touch in the first year and extensive affectionate touch thereafter; on request breastfeeding for several years; warm responsiveness to needs from mother and then by a small community of caregivers; self-directed play in the natural world with multi-aged playmates; and positive social support with no physical punishment (Hewlett and Lamb 2005).

Why does the nest matter? At full-term birth (40–42 weeks of gestation), a human baby emerges with only 25% of adult brain volume, which grows especially rapidly in the first year with 90% in place by age five (Trevathan 2011). In fact, newborns look and act like fetuses of other

animals till about 18 months of age. Thus, many physiological and social systems are shaping themselves during the sensitive prenatal and postnatal periods, including the stress response, endocrine systems, neurotransmitters, immune system, and capacities for social engagement (Narvaez et al. 2013b). How well these develop is influenced by the quality of the nest.

In primal societies, the evolved nest is provided without resistance or question – adults cooperate with the needs of the child. A community of responsive caregivers provide what babies and young children need, even sharing breastfeeding (Hrdy 2009). Primal societies display a deep trust in natural processes (Ingold 2005). By providing the evolved nest, they ensure human propensities for cooperation are developed, a leading source for successful evolution (Weiss and Buchanan 2009), especially human evolution (Tomasello et al. 2012).

Civilized societies do not provide the evolved nest, and if a component is provided it is usually partial or degraded. For example, breastfeeding might occur but only for a short duration (less than a year) rather than for an average age weaning of 4 years as found among small-band hunter-gatherers (Hewlett and Lamb 2005). Instead of providing what babies evolved to need, civilized societies display a deep *distrust* in natural processes related to nest components and child raising. Civilized nations tend to work against natural processes instead of with them. The costs to social development are deep and wide, from poor health to poor sociality and the reliance on evolutionarily more primitive brain systems to survive (Narvaez 2014).

Social Development in Primal Societies

How does a child learn to be a human being? Primal societies know it takes some time. In primal societies, children are assumed to be autonomous agents who are learning to be fully human within the community and can take charge of their own learning (for review, see Narvaez 2013). Children follow evolved innate programs that guide them in learning to live within their society, mimicking models, and practicing what they are

motivated to practice at the particular age – as babies, apart from feeding and sleeping, primarily social feeling and social routines for how to start and carry on conversations, share eye gaze and play. Initially, self-regulation and sociality are guided by foundational interactions with adults and other caregivers, shaping physiological systems. For example, responsive care (meeting the needs of the baby in a timely, warm manner) fosters a well-functioning stress response (one that is not easily triggered nor mute from excessive distress) and a well-functioning social engagement system of the vagus nerve (Lupien et al. 2009; Porges 2011, 2017).

Adults provide support without interfering in the unfolding development of the young child. Primal societies avoid coercion at any age, understanding that it can undermine the normal trajectory of development, undermining self-confidence and increasing dependence on others for self-direction. Coercion or punishments are avoided as they can do damage to the developing spirit of a child. Throughout childhood, children learn without schooling, a “natural pedagogy” where younger imitate older and older guide younger and the skilled guide the unskilled through apprenticeship (Rogoff 1990).

Becoming a good human being is the goal among primal societies (Narvaez 2013). What does that look like? Adults are expected to cooperate in all sorts of ways (Hill et al. 2011). For example, they share food and resources without resistance, act with others in mind, enjoy socializing virtually all the time, not coerce others but be highly autonomous; in fact, SBHG adults around the world, no matter their culture, are typically described as independent but also communal, calm, and content but also generous (Ingold 2005). The evolved nest may provide a “cultural commons” for the development of these shared personality characteristics, and sociomoral capacities for relational attunement and communal imagination (Narvaez 2014, 2018). Other social practices are common in these societies. For example, when an individual starts to get a big head (e.g., a successful hunter), the group teases him relentlessly (e.g., “it’s such a tiny animal, we should go find a rabbit instead”) until he bursts into laughter and the puffed-up ego is deflated (Lee 1979).

Optimal social development is expected for individuals in primal societies and their survival may have depended upon it. But fitting well into the human society is not enough to be a good human being. It is expected that grown individuals will act with the biocommunity in mind, the place on the earth in which one’s lifecourse is embedded, and include respect for the wellbeing of entities in the natural world. One must maintain proper relations with all entities (e.g., animals, plants, rivers) in an ongoing dynamic manner, that is, being present and responsive to what is unfolding in the human and other-than-human lifeworlds (Ingold 2005, 2011). Interestingly, the capacity to receptively attend to the living world – its sentience, communications, and relationships – is initially governed by right-brain hemisphere capacities, which develop rapidly in early life, when the evolved nest is especially influential.

Primal societies, including native American tribes, display a companionship orientation to raising children and living on the earth (Narvaez 2014), a place considered sacred and moral (Redfield 1953). Because an individual’s actions are impactful on the wellbeing of the whole biocommunity, they must be taken with respect and awareness. Elders typically display social engagement, wisdom, and communal morality and guide social development of the community through story and ritual (Deloria 2006).

In summary, primal societies provide a species-typical developmental system for raising the young. Even beyond the evolved nest for early childhood, they provide a continuum of support throughout life, including the transition to adulthood and maintaining connection to the cosmos through ritual and trance. It is rare for a child not to develop into full humanity.

Social Development in Civilized Societies

In civilized nations, socialization is often discussed as “the processes whereby naïve individuals are taught the skills, behavior patterns, values, and motivations needed for competent functioning in the culture” (Maccoby 2015, p. 3). Notice the focus on adults “teaching” and

controlling children. It is assumed that children must be pressured into fitting in. This typically involves coercion of some kind (corporal or psychological punishment). Punishment may be needed to overcome the natural egalitarianism and expectation for companionship and respect young children display (Fehr et al. 2008; Trevarthen 2005), making them feel more insecure and more prone to comply with adult directives.

Child raising advice for centuries has advocated harsh treatment in early life, treatment that breaks the spirit of children in order to control them for life (because the early years of experience won't be consciously remembered later; Miller 1983). Civilization has a long history of harsh treatment. Lloyd deMause (1974) described six historical phases reflecting changing parent attitudes towards children, moving from *infanticide* (antiquity to fourth century AD) to emotional or physical *abandonment* (fourth to thirteenth century) to *ambivalence* (fourteenth to seventeenth centuries) where children were beaten into shape, followed by *intrusive* parenting (nineteenth century), when empathy emerged, but there was still a focus on controlling the child in every way, *socialization* (nineteenth to twentieth centuries) to channel impulses – as proposed by psychodynamic theorists who emphasized the control of innate aggressive and sexual impulses, later morphing to a focus on self-regulation – indeed, radical behaviorism emphasized the conditioning of good habits from an early age, like baby independence, because as young adults it would be required (Watson 1928). Finally, deMause identified a *helping* orientation (mid-twentieth century till present) where parents became involved in empathizing with and fulfilling child needs.

Still today, parental control and obedience are dominant goals for young child raising in civilized societies. Note the popular theory of parenting styles proposed by Diana Baumrind (1967), who favors parental control. She distinguished four basic styles: authoritarian (high demandingness, low responsiveness), authoritative (high demandingness, high responsiveness), permissive (low demandingness, high responsiveness), and uninvolved (low demandingness, low responsiveness). Among individualistic societies like the

USA, the authoritative style leads to greater child success as measured by the middle-class values of society (i.e., school achievement, work success) (Baumrind 1971a). However, a subset of families did not fit Baumrind's model (Baumrind 1971b). She called them "harmonious" parents. They were only moderately demanding, highly responsive but also highly tolerant. She noted that preschool girls thrived but that preschool boys seemed feminized in those families (i.e., submissive rather than rebellious). This mode and outcomes are more aligned with primal society.

What does social development look like in a civilized society? There is a great deal of variability in specifics, but gender roles tend to be more rigid than in primal societies; there are often class and racial differences, made explicit, or enforced implicitly; and if a person does not stay within the correct pathway, the individual can be ridiculed or even ostracized and killed (Turiel 2002). So, obedience to prescribed ways of being is a primary aim, wanting for self what society wants for the self and learning to avoid stepping out of bounds. In individualistic, consumerist societies like the USA, the goal for a middle-class child is success in school where entrepreneurial, rebellious, and creative skills (within the confines of the worldview) are encouraged. These lead to a good-paying, high-status job within the system. In contrast, often lower-class children are socialized through the hidden curriculum to follow rules and authority, skills for low-grade factory or service work (Freire 1970; Kozol 1991; Jackson 1968).

Traditional pedagogy holds the view that reasoning and explicit conscious knowledge guide behavior and so adults directly teaching rules of moral behavior is considered an effective way to socialize a child (Dewey 1908). This view of learning has led to all sorts of difficulties, such as incongruence between explicit knowledge about the right way to behave and actual behavior. If the child disobeys the rules, it is considered the child's fault. In reality, children learn from immersed experience – they initially construct their patterns of behavior from the sensorimotor routines that work in their family contexts, using these implicit notions to guide their lives (Varela

1999). Children especially learn from how they are treated, imitating what adults do, not so much what adults might say otherwise to do.

In the late twentieth century, rather than focusing on the development of moral reasoning (Kohlberg 1969), psychology researchers began to focus on the development of prosocial emotions (e.g., empathy) and helping behavior as central to social development (Eisenberg 2000). The social capacities needed include not only self-control (not aggressing against others, not withdrawing) and complying with rules, but sufficient empathy with and sympathy for others and skilled cooperation (flexible getting along). But the trends for the USA as a whole on these characteristics have been going in a downward direction for perhaps 50 years. Many children and adults have difficulty with self-regulation, display low empathy, and lack responsive social skills (Narvaez 2017). Early life stress fosters self-disorganization and physiological systems that are threat reactive, leading to habitual externalizing (aggression toward others) and/or internalizing (depression and withdrawal) (Shonkoff et al. 2012). Children raised outside the evolved nest necessarily represent species atypical development. Many do not reach their potential but are dominated in their sociality by more primitive survival systems.

As a result, psychological science has been examining possible sources of failure and success to socialize children to be cooperative and contributing adult members of civilized society. Interestingly, components of the evolved nest are factors that foster success. The most widely studied is caregiver responsiveness (Maccoby and Martin 1983). Neuroscientific studies are supporting the emphasis on early life relational attunement with caregivers and the development of secure bonding and attachment (Schore 2000). A child treated with reciprocal mutual respect, empathy, and cooperation develops those same characteristics over the long term, including identifying as a moral self (Kochanska 2002; Thompson 2012). When the social ecological contexts coordinate relational support for a child, resilience (avoiding risky behaviors) and thriving are more likely (Bronfenbrenner 1979; Lerner et al. 2003; Scales and Leffert 1999). Other components of the evolved nest also appear to shape

empathy, conscience, and cooperation (Narvaez et al. 2013a, c).

It should be noted that basic aspects of social development like self-control and social interest are impaired by nonsocial factors that occur in developmental contexts, like pollutants (e.g., lead, mercury, plastic), which are released into mother's bodies and children's environments by civilization's practices (e.g., Liu and Lewis 2014).

Optimal social development in civilized societies is contested. Some societies value autonomy, whereas others emphasize community values or respect for a divine order (Jensen 2011). Moreover, as societies have undermined provision of the evolved nest and pathologies have multiplied, there is no agreement on baselines for raising children. If there is interest in the question of baselines for raising young children in advanced societies, there is little agreement on what optimal development looks like. Part of the reason is that science has taken over knowledge systems to such an extent that people feel they cannot "know" something without an experiment to show it. At the same time, science typically prides itself on being value-neutral and does not wish to weigh in on value questions like parenting. Nevertheless, advanced nations are often under the thumb of science-wedded-with-technology which values detachment and machine-treatment of human beings and control of human life by technology (Mumford 1967; Postman 1993), despite the fact that scientific theories have moved to dynamic interactionism (Kauffman 2016). Civilization's system of controls requires conformist human natures and not the free spirits of normal, species-typical human beings (Fromm 1964). As a result of confusion about raising children and the nature of human nature, Westernized societies are looked at askance by traditional societies (Sahlins 2008).

Differences Between Civilized and Primal Societies

There are several key differences between primal and civilized nations that play a role in social development. In civilized societies where childhood experiences vary widely, there is frequent discussion of "nature" versus "nurture" in

determining child outcomes. Of course, this is a false dichotomy for a dynamic system that is a human being, whose self is biosocially constructed (biology is co-constructed by social experience, and social capacities are shaped by that biology; Ingold 2013). In contrast, in primal societies the evolved nest is provided universally to young children. The focus of development is on empowering the child's unique spirit. The basic assumption is that, with proper support, every child will be a cooperative member of society.

Whereas in primal societies, the village raises the children, in civilized nations the initial task and responsibilities reside most often with parents alone (and even with a single parent), at least until schooling. Parents are often isolated, highly stressed and even depressed in individualistic societies, unless government programs build in different types of support (e.g., parental leave after birth, nurse visits, government-subsidized daycare) (Lally 2012). Because parental responsiveness is fundamental to good child outcomes, the lack of support means that children are unlikely to develop their full human potential.

As a result of early life stress, the Westernized world has undermined the development of the right hemisphere, which is scheduled to develop rapidly in the first years (Schore 1994). Lack of appropriate care leads to the underdevelopment of right-hemisphere-directed self-regulatory, social and receptive capacities, which are difficult to repair later. The undermining of right hemisphere development may be cause and consequence of the Western world's capture by left-hemisphere thinking, shaping society to be the detached-from-nature culture it has become (McGilchrist 2009), guided by a worldview that life and the cosmos generally are amoral, disenchanted, and fragmented (rather than moral, sacred, and unified (Four Arrows 2016; Redfield 1953).

In primal societies traditionally, the group focuses on living well in that place on the earth, and it is the elders who have lived experience to guide the community in living well and sustainably in the particular landscape. In civilized nations, rapid technological change means that parents and children are often focused on adopting and managing the latest technologies, and the

children do that better, reversing the roles of who learns from whom. Perhaps as a result of missing elder wisdom, civilization has shifted to values of technological efficiency over human values (Postman 1993). Civilization spends a great deal of energy focusing on preventing immediate bad outcomes for privileged humans, using coercion to enforce norms of hierarchy and obedience to the system, at the expense of biocultural diversity (Christen et al. 2017).

Most research on child social development is done in civilized societies or at least with their constructs about what is important. Baseline assumptions about human nature and about children guide research paradigms and interpretations. Cultures that believe humans are basically evil will think it is necessary to use coercive techniques in parenting and socialization. If you assume humans are naturally selfish and aggressive, then parental control will be considered vital for social development properly carried out, necessary for self control over natural impulses. In contrast, if you think humans are basically good, then you would be more likely to let development occur without too much interference, as in primal societies (Rousseau 1979.) Assuming that humans naturally grow into cooperative community members, you expect cooperation to emerge over the course of development given proper support. When social development goes awry, the explanation will be different depending on the baseline assumptions one has about human propensities. In the first case, not enough force (reinforcement, punishment) was used by adults to shape the child. In the second case, not enough support was provided to allow the natural course of development to take place or trauma was experienced that led the child's development astray.

As noted, over the course of civilization, adult treatment of children has shifted (deMause 1974). Researchers too have shifted in their assumptions, moving increasingly toward the view that children are naturally cooperative with proper support, and that lack of support or trauma can undermine normal social development. The sciences generally are moving to the view that humans, like all living things, self organize around experience (Kauffman 2016). If early experience guides the shaping of

physiological systems and social capacities, social support including the evolved nest, may be necessary for social development as a human being.

Social Development in Nonhuman Primates

Dario Maestripieri

Department of Comparative Human Development and Institute for Mind and Biology, The University of Chicago, Chicago, IL, USA

Synonyms

Growth; Maturation; Primates

Definition

Changes in the social behavior of nonhuman primates from birth to adulthood.

Introduction

Research with nonhuman primates can provide valuable insights into two main aspects of child development: normative development and interindividual variation. These insights can be mainly theoretical, empirical, or both.

Normative Development

Nonhuman primate research can potentially inform many different theoretical and empirical aspects of normative child development, including socio-behavioral development, cognitive

development, communicative development, emotional development, and physiological development as well as various normative aspects of parent-child relationships including attachment, parent-child conflict, and others. Historically, the main contributions of nonhuman primate research to our understanding of normative child development have been in the context of parent-child relationships. Specifically, nonhuman primate research played a pivotal role in John Bowlby's formulation of attachment theory (Bowlby 1969).

Bowlby derived from ethology the notion that a comprehensive theory of attachment should account for this phenomenon at different levels of behavioral analysis: causation (the endogenous conditions and external stimuli that activate attachment), ontogeny (the development of the attachment system in infancy and throughout the life span), function (the adaptive value of the attachment system), and phylogeny (the evolutionary continuity in attachment across humans and the other primates) (Maestripieri 2003). In addition to conceptual contributions to attachment theory, observations of mother-infant interactions in captive rhesus macaques conducted by Robert Hinde and coworkers provided important insights into developmental changes in the attachment system, responses to maternal separation and potential threats, and exploration and secure base phenomena (Hinde 1974). Hinde and coworkers documented the quantitative changes in time spent in contact and proximity and in the mother's and infant's roles in maintaining contact and proximity. These studies revealed that the developmental changes in mother-infant interactions during the first few months of infant life are remarkably similar across different populations and environments, suggesting that there are modal developmental curves for mother-infant interactions that are characteristic of all old-world monkeys. Hinde introduced Bowlby to the work of Harry Harlow, which experimentally demonstrated the primary role of the caregiver as a source of contact/comfort and protection rather than nutrition (Maestripieri 2003). Thus, research on primate behavior played a crucial role in outlining the normative aspects of human attachment theory.

In terms of normative development of attachment in nonhuman primate infants, there is good experimental and observational evidence that monkey infants (1) gradually discriminate their mother, or more generally their primary caregiver, from other individuals, (2) selectively direct their attachment behaviors toward this individual, (3) show distress and anxiety when separated from this individual, (4) use this individual as a secure base for exploring the environment, and (5) as a safe haven when they are frightened or in distress (Maestripieri 2003). Essentially, nonhuman primate infants possess an attachment system whose normative aspects are very similar to those of human attachment. In particular, the attachment system appears to serve a similar biological and social function in nonhuman primate and human infancy and appears to be regulated by similar exogenous and endogenous factors. There may also be some obvious differences, however. The extent to which nonhuman primate infants develop a representational model (i.e., an internal working model) of the caregiver in relation to the self and the external environment is not clear. Other differences between nonhuman primate and human attachment likely involve the ontogeny of the attachment system and the timing with which it and its components mature and/or become activated. The ontogeny of the attachment system, and to some extent also its proximate regulation and adaptive function, is likely to vary not only between humans and other primates but also among the over 300 nonhuman primate species, in relation to the life history of the species and its specific ecological, social, and reproductive adaptations.

In nonhuman primate research, the study of normative attachment processes has also been conducted by examining infant behavioral and physiological responses to separation from the mother (Maestripieri 2003). Early studies focused on the infant's behavioral responses to separation. Such studies documented the occurrence of an initial phase of "protest" followed by a phase of "despair," similar to those observed for institutionalized children. A third phase of detachment observed in children following the reunion with their caregivers has not been observed in

nonhuman primates. Separation studies have gradually incorporated more physiological variables (e.g., heart rate and body temperature, hormones and neurotransmitters, immunological measures) and more sophisticated techniques of measurement. Subsequent developments of this area of research have included postmortem studies of brain anatomy in maternally separated and/or socially deprived monkeys. The rationale underlying the study of infant responses to separation was, at least initially, the notion that the occurrence of a response to separation would provide information about the existence and strength of an attachment bond. Response to separation from the caregiver is an important component of attachment theory, and the occurrence of a separation response may indeed provide evidence of the existence of an attachment relationship. Beyond showing that separation is stressful, however, the contribution made by separation studies to research on normative attachment is unclear.

While research on normative aspects of attachment in nonhuman primates preceded, informed, and even guided human research on normative aspects of attachment, the opposite was true for research on normative aspects of socio-behavioral development, cognitive development, communicative development, emotional development, and physiological development. In these cases, human research typically preceded, informed, and guided nonhuman primate research. Other than showing that some aspects of normative child development are not unique to the human species but are also shared by other primate species, the contributions of nonhuman primate research have not been highly significant.

Interindividual Variation

The contributions of nonhuman primate research to our understanding of interindividual variation in child development have been mainly empirical, not theoretical. Studies of attachment in nonhuman primates have often addressed individual differences in the development and expression of attachment but almost exclusively in the context

of infant behavioral and physiological reactions to maternal separation. For example, these studies have documented variability in the intensity of the “protest” response to separation and in the extent to which such response is followed by withdrawal and depression. It has been shown that individual differences tend to remain consistent across repeated separations and reunions and stable throughout major periods of development. Stable individual differences in behavioral and physiological responses to social separation have also been found among rhesus macaques reared with surrogate mothers, notably peers.

In nonhuman primates, individual differences in response to separation are accounted for by both heritable and experiential factors. Although the study of genetic influences on behavioral development and stress reactivity in nonhuman primates is a relatively new area of research, a growing body of evidence has already accumulated about the importance of gene polymorphisms involved in emotion regulation and, in particular, of *5-HTTLPR* (serotonin transporter), *OPRM1* (opioid receptor), and *DRD4* (dopamine receptor). The effects of these polymorphisms often interact with each other and with early experience, such as exposure to stress in the first few months of life. The mechanisms underlying main genetic effects on behavior or gene-environment interactions are still poorly understood, but research on epigenetics appears to be particularly promising. Although systematic research on the effects of genes and early experience in nonhuman primates has been conducted with a very limited number of species, it is highly likely that the results of this research are generalizable to humans (Coyne and Maestripieri 2016).

A different line of nonhuman primate research has investigated the role of the mother’s own behavior toward the infant, namely, her parenting style, as a source of interindividual variation in both socio-behavioral development and reactivity to stress (Clancy and Hinde 2013). Variation in artificial rearing conditions in the laboratory (e.g., rearing infants with or without their mothers, with peers, and under various conditions of social deprivation or social enrichment) can also affect the

development of behavior and reactivity to stress. Nonhuman primate studies have shown that exposure to variable levels of maternal protectiveness and maternal rejection experienced in early infancy affects variation in infant independence from the mother and infant tendency to explore the environment or respond to challenges at various ages. Infants reared by highly rejecting (or less responsive mothers) mothers generally develop independence at an earlier age (e.g., spend more time out of contact with their mothers, explore the environment more, and play more with their peers) than infants reared by mothers with low-rejection levels. In contrast, infants reared by more protective mothers appear to be delayed in the acquisition of their independence and are relatively fearful and cautious when faced with challenging situations. Effects of maternal style and other aspects of the infant’s early social environment have also been documented with regard to responsiveness to negative visual stimuli (e.g., threatening facial expressions). Studies have shown that rhesus infants reared by more protective mothers and those reared by high-ranking mothers exhibit a stronger attentional bias toward faces with threatening expressions, as opposed to faces with neutral expressions, when compared to infants reared by less protective mothers and those reared by lower-ranking mothers (Coyne and Maestripieri 2016).

The issue of whether these effects of early experience on infant reactivity to the environment also persist into later stages of development and adulthood has been addressed by a few studies, and the results have been mixed (Coyne and Maestripieri 2016). The best evidence for long-term effects of early exposure to variable parenting style in infancy has been provided in the context of intergenerational transmission of parenting style in female monkeys. Here research has shown that there are similarities in maternal rejection rates and in the propensity to display physically abusive parenting behavior between mothers and their adult daughters. Studies of this phenomenon using a cross-fostering experimental design have shown that early experience, rather than genetic similarities between mothers and daughters, plays a crucial role in the

intergenerational transmission of parenting style. However, the contribution of genetic predispositions for particular personality traits or other psychological and behavioral characteristics cannot be ruled out. Although cross-fostering experiments are difficult to conduct in humans, many human longitudinal studies of child development in large pedigreed populations, or in which data on adopted children or twins are available, have confirmed that both early experience and inherited genetic predispositions play an important role in the origin of individual differences in child development. Although non-human primate research could potentially make significant theoretical and empirical contributions to human research on interindividual variation in child development, this potential remains yet to be fully realized.

Conclusion

Nonhuman primate research has contributed in the past to our understanding of many fundamental aspects of early child behavioral development (e.g., the discovery of the attachment system and its role in mother-child relationships and in the acquisition of independence). Thus, in the future, it has the potential to enhance our knowledge of many other aspects of development including, for example, brain-behavior relationships early in life and how these relationships are affected by genes and environment (Coyne and Maestripieri 2016). Nonhuman primate research offers the opportunity to perform biological and environmental manipulations that would be difficult or impossible in humans. It also provides the opportunity to longitudinally investigate developmental processes across an individual's lifespan and generations in a relatively short period of time. Finally, by studying and comparing developmental processes across a number of primate species in relation to their phylogenetic history, non-human primate research can help us understand the extent to which many aspects of human development are unique to our species or shared with other species by virtue of our common evolutionary history.

Social Disabilities

Ashlan Prince
University of South Carolina – Beaufort,
Bluffton, SC, USA

Synonyms

[Autism spectrum disorder](#); [Rett syndrome](#); [Social anxiety disorder](#); [Social communication disorder](#)

Definition

Impairment in social functioning including but not limited to anxiety caused by social situations

or lack of ability to form or understand relationships. Autism spectrum disorder is commonly thought of when referring to social disability.

Introduction

There is no specific DSM-V classification of social disability; despite this, there are disorders that negatively influence social behavior and therefore may be considered social disabilities. These disorders, which are often categorized as *pervasive developmental disorders* (PDDs), delay or inhibit the socialization and development of communication in humans (American Psychiatric Association 2013). The PDD category includes disorders such as Autism Spectrum Disorder (ASD) and Rett syndrome. However, there are other disorders, such as social communication disorder and social anxiety disorder that are not considered part of the PDD category but still negatively influence social behavior. This entry will describe the symptoms and potential causes of the following social disabilities: ASD, Rett syndrome, social communication disorder, and social anxiety disorder.

Autism Spectrum Disorder

ASD refers to a continuum of social disability symptoms – listed on the continuum in order of prevalence and severity. Because this spectrum encapsulates a variety of social impairments, ASD may be viewed as the social disability that affects the most people. ASD is considered part of the PDD diagnostic category and contains many disorders that may be considered social disabilities. For instance, individuals on the mild end of the Autism spectrum are often diagnosed as having Asperger's syndrome. Asperger's syndrome differs from ASD in that individuals with Asperger's may attempt social situations but are often perceived as being socially awkward.

Individuals with ASD experience lifelong impairment of social functioning. ASD affects about 1% of the population and is approximately 4.5× more common in boys compared to girls

(American Psychiatric Association 2013; Center for Disease Control and Prevention 2017). There is a wide range of difficulties associated with ASD, ranging from mild social impairment to the inability to care for oneself without assistance. Arguably, one of the most debilitating social impairments caused by ASD is the inability to understand relationships or display social-emotional reciprocity (American Psychiatric Association 2013). Other symptoms common in ASD patients include strong fixated interests, issues with sensory input (e.g., sensitivity to fabric in clothing), and insistence on “sameness” or extreme consistency and familiarity within one's social environment (American Psychiatric Association 2013). It is not unusual for ASD to be comorbid with intellectual disabilities, although some individuals with ASD may have above average intelligence (American Psychiatric Association 2013).

The most commonly used treatment for ASD is Applied Behavioral Analysis (ABA), which rewards positive behaviors and discourages maladaptive behaviors. There is a growing trend within school environments to utilize ABA therapy to treat students with ASD (Center for Disease Control and Prevention 2017). ABA essentially uses operant conditioning to influence behavior, as individuals generally make connections about behaviors and their consequences (Mash and Wolfe 2016).

While there is no known exact cause of ASD, researchers have found several links between ASD and various potential biological and environmental determinants that has helped shed light on the potential cause(s) of ASD. For instance, twin studies have shown that there may be a genetic component, and that the disorder is comorbid with chromosomal disorders such as Down syndrome or Fragile X syndrome (Center for Disease Control and Prevention (2017). Researchers have also found a link between elevated testosterone levels and ASD symptoms – indicating that children with ASD may possess an “extreme male brain” that causes these ASD patients to lack empathy and interest in social relationships (Baron-Cohen 2002). Other data has revealed that children from obese mothers

are at an increased risk of being born with ASD (Li et al. 2016). Scientists across the world continue to research ASD in hopes of finding the exact cause(s) and better treatments.

Rett Syndrome

Rett syndrome is somewhat similar to ASD in presentation. It is a rare neurological developmental disorder that is more prevalent in females; in males, it is normally fatal during infancy, but in rare cases, it may present as a milder form of what occurs in females (Mayo Clinic 2018). Individuals with Rett syndrome develop normally until about 6 months of age; at this time, there is a regression of milestones that marks the beginning of the first of four stages of progression (Mayo Clinic 2018). The second stage occurs between 1 and 4 years of age and features slow head growth, problems with motor skills, continued degeneration of social skills, and hyperventilating or screaming without reason (Mayo Clinic 2018). The third stage is considered a plateau, which may occur between 2 and 10 years. There may be some limited social improvements but seizures generally begin to occur during this time (Mayo Clinic 2018). The fourth and final stage of Rett syndrome generally begins after 10 years of age and features continued motor degeneration (Mayo Clinic 2018).

Experts believe Rett syndrome is caused by random mutations on the MECP2 gene, although some cases appear to be inherited (Mayo Clinic 2018). Researchers suspect the gene interferes with protein production involved in brain development, but the reason for the development of the disorder is unknown (Mayo Clinic 2018). There is no cure for Rett syndrome nor is there a known way to prevent the disorder. Current interventions for the disorder focus on communication and motor skills (Mayo Clinic 2018).

Social Communication Disorder

Social communication disorder, also called social pragmatic disorder, is similar to ASD in nature but

lacks the presence of restricted behavior patterns, interests, or activities (American Psychiatric Association 2013). Key features of social communication disorder include difficulties understanding “rules” of conversation and storytelling, along with difficulty understanding things not explicitly stated (American Psychiatric Association 2013). Diagnosis of the disorder is unusual under the age of 4 years old but may not be realized until adolescence when the individual struggles to understand complex conversation or interactions (American Psychiatric Association 2013). Individuals with social communication disorder may display similarities to social anxiety disorder symptoms, attention-deficit/hyperactivity disorder, and intellectual disabilities. A family history of ASD and specific learning disorder may increase chances of being born with social communication disorder (American Psychiatric Association 2013).

Social Anxiety Disorder

Unlike the preceding disorders, where there is a lack of understanding of social interaction, patients with social anxiety disorder possess an intense and persistent fear of social interaction. For an individual to be diagnosed with social anxiety disorder, his/her fear of social interaction must be out of proportion for the situation; for juvenile patients, their fear of social interaction must not be limited to conversing with adults (American Psychiatric Association 2013). This fear of social interaction is persistent over a long period and causes dysfunction in one’s daily life. However, to be diagnosed with social anxiety disorder, the patient’s fear and anxiety must not be caused by other disabilities such as ASD (American Psychiatric Association 2013).

Social anxiety disorder is more prevalent in women, and onset typically occurs around 13 years of age (American Psychiatric Association 2013). Social anxiety disorder is distinctly different from agoraphobia in that the fear is of judgment by others, not the inability to escape the situation (American Psychiatric

Association 2013). As noted before, social anxiety disorder has similarities to social communication disorder, and these symptoms are also found in children with ASD as well (American Psychiatric Association 2013).

Conclusion

Although this entry focused on four specific social disabilities, it is important to note that social disabilities are not necessarily limited to ASD, Rett syndrome, social communication disorder, and social anxiety disorder. ASD features social difficulties along with stringent interest and insistence on sameness. Rett syndrome presents similar symptoms to ASD but features severe motor degeneration along with the social impairment. Social communication disorder presents with similar social difficulties to ASD but does not feature symptoms such as stringent interest. Social anxiety disorder includes fear of social situations, although there is ability to understand the social situation. There is no ubiquitous system of accommodations in place strictly for individuals with social disabilities in schools. However, school administrations can grant accommodations to socially disabled students if they possess certain comorbid intellectual disorders, learning disabilities, or PDDs.

Social Dominance and Sexual Access

Isaac Ligoeki
The Ohio State University, Columbus, OH, USA

Synonyms

[Reproductive skew](#); [Resource holding potential](#)

Definition

In many social systems, individual access to reproductive opportunities is moderated by dominance status within the social group.

Introduction

Achieving and maintaining dominance status within a group are assumed to be energetically costly and at least in the short term require engagement in conflict or agonistic interactions at the expense of other behaviors. In the long term, however, dominance status is often associated with greater access to food and other resources, as well as greater opportunities for reproduction and ultimately fitness gains. For many species associations between dominance status and reproductive success are clear, although relative importance of access to mates versus other advantages of dominance status (such as food resources or shared parental care) varies within and between species.

Dominance and Resource Holding Potential

Social dominance is commonly associated with resource holding potential (RHP; Parker 1974) such that individuals possessing traits which equip them for success in aggressive or agonistic interactions have greater access to resources. RHP (and by association, dominance) has been framed in the context of conflict over food resources, shelter, and access to mates and reproductive opportunities.

Among the many cases in which social dominance is associated with reproductive success, access to mates is in many cases influenced by dominance status through several behavioral and physiological mechanisms.

Mate Choice

While greater resource holding potential may explain some cases of socially dominant individuals being able to monopolize reproductive opportunities, access to mates may also be moderated through sexual selection and preference for socially dominant individuals. Preference for dominant mates has been suggested to be selected for either due to direct fitness benefits (through resources, protection from harassment) or due to

indirect fitness benefits for offspring such as parental care or good genes. In wide-ranging species, individuals capable of acquiring and maintaining dominance status also have “good genes” which are associated with resource holding potential, elaborate morphological features and behaviors associated with reproduction, and higher overall fitness. In cricket *Gryllus bimaculatus*, dominant males had higher immunocompetence which may explain female preference for them (Rantala and Kortet 2004). In chimpanzees, *Pan troglodytes*, priority of access by dominant males was predictive of reproductive success, but that of subordinate males did frequently reproduce “low-quality” females (Wroblewski et al. 2009). However, in many cases an apparent preference for dominant mates may not solely result from a preference for dominance. For example, Lynch et al. (2012) hypothesized that female preference for large males in the coercively mating mosquito fish (*Gambusia*) may have more to do with avoiding the advances of smaller males than an actual preference for large males.

Glucocorticoids and Their Impact on Reproductive Processes

Glucocorticoid hormones have many important functions in vertebrates but are perhaps best known for their role in stress-response pathways through which glucocorticoids activate and reallocate energy toward skeletal muscles, eyes, and respiration rather than toward functions such as reproduction or digestion – commonly referred to as the “fight or flight” response. In many animal groups, subordinate group members may have chronically elevated glucocorticoid hormone levels which in some cases can inhibit other hormonal pathways associated with reproduction. Thus, either through social dynamics or overt aggressive interactions, the reproductive capacity of subordinate group members can be reduced.

The Importance of Reproductive Skew

Cooperatively breeding societies and many dominance-structured animal groups present a

unique scenario to examine the relationship between dominance and access to mates. A key defining characteristic of cooperatively breeding societies is that dominant individuals have greater access to mates and thus generally greater reproductive success than subordinate group members. Subordinate group members that attempt to reproduce may face harassment, eviction, or infanticide. While reproductive skew is typically high in cooperatively breeding groups, dominant individuals may concede reproductive opportunities to helpful subordinate individuals under the “concessions model” framework which has empirical support in a number of species including gelada baboons (Snyder-Mackler et al. 2012) and the cichlid fish *Neolamprologus pulcher* (Heg et al. 2009).

For many primate and non-primate societies, female social status is associated with reproductive output although this relationship is likely more heavily influenced by social connections rather than access to mates.

Dominance, Sexual Access, and Human Societies

Like in many other animal species, there is abundant evidence that socially dominant humans also have greater reproductive success. For males in both pre-modern and modern civilizations, dominance is associated with reproductive success, although this relationship is likely moderated by resource holding potential and access to resources, and also confounded by wealth and education. Additionally, there is evidence of a role for sexual selection as Havlicek et al. (2005) found female human subjects preferred the odor of “dominant” men during the fertile period – particularly females in stable relationships.

Studies on humans have drawn distinctions between dominance (determined by direct dyadic conflict) and prestige (social status) and found a general trend that heterosexual women prefer males with high prestige rather than dominance (Snyder et al. 2008). However, von Rueden et al. (2010) drew distinctions between dominance and prestige and found that both are important predictors of the number of

within-pair offspring as well as extra-pair affairs in the Tsimane people.

Conclusions

The relationship between dominance and access to mates has been of interest to evolutionary psychologists, primatologists, and behavioral ecologists for decades. In humans and nonhuman animals alike, apparent relationships between dominance and reproductive success have been well documented in many taxa. Having access to mates is one mechanism through which the relationship between dominance and reproductive success could be manifested. In many cases, these relationships may actually have less to do with access to mates and instead be more heavily influenced by differential access to other resources such as food or habitat or other factors such as social stability.

Definition

Social dominance orientation is a measurement of “the general desire to establish and maintain hierarchically structured intergroup relations regardless of the position of one’s own group (s) within this hierarchy” (Sidanius et al. 2016, p. 152).

Introduction

Human societies tend to structure themselves as group-based social hierarchies such that some groups enjoy greater access to fitness-relevant resources such as prestige, wealth, social status, healthcare, food, homes, mates, and so on. Social dominance theory (SDT, Sidanius and Pratto 1999) asks the questions why and how group-based hierarchies are continuously reproduced, at least among surplus-producing societies. The theoretical framework spans macrostructural, institutional, ideological, social role, individual, and behavioral genetic levels of analysis to address this question and postulates that humans have a predisposition to navigate group-based social structures (Kleppetø et al. 2019; Kunst et al. 2017; Pratto et al. 2006; Sidanius et al. 2016; Sidanius and Pratto 1999).

Conflicts between groups are ubiquitous across history and cultures. Ideologies that justify beliefs about the superiority of dominating groups might serve the function of reducing conflicts by legitimizing the hierarchical status quo (Pratto et al. 1994; Sidanius and Pratto 1999). According to SDT, when these ideologies are widely accepted within a society, they justify discrimination and allow some groups to dominate over others based on their gender, age, and, especially, socially constructed markers of group membership such as class, race, ethnicity, caste, and religion – what SDT coins arbitrary sets. The beliefs and ideologies that justify dominance hierarchies are called hierarchy-enhancing legitimizing myths; examples are the “divine rights of kings,” sexism, and the Protestant work ethic suggesting that you get what you personally deserve (myths in this context mean widely shared ideologies, not implying that they are

false or true). Beliefs that justify flat or egalitarian group structures are called hierarchy-attenuating legitimizing myths, examples being the universal rights of man, socialism, and feminism (Sidanius et al. 2016; Sidanius and Pratto 1999). Importantly, SDT postulates that particular instances of modern group-based discrimination such as racism, classism, sexism, and nationalism are manifestations of more general processes where dominant groups maintain social, economic, and military supremacy over subordinates (Sidanius et al. 2016).

At the individual level of analysis, endorsement of such intergroup dominance hierarchies is reflected in the individual difference of *social dominance orientation* (SDO) (Ho et al. 2015; Pratto et al. 1994) to which we now turn our attention. This general relational motive to enhance versus attenuate between-group hierarchies has proven one of the most robust predictors of intergroup attitudes (Pratto et al. 2006; Sidanius et al. 2016; Sidanius and Pratto 1999), from support for social welfare to ethnic persecution of immigrants (Dunwoody and McFarland 2018; Ho et al. 2012, 2015; Thomsen et al. 2008). Here, we discuss the conceptual and psychometric properties of SDO, and we highlight some key evolutionary forces that might explain SDO's inter-individual variation and mean-level sex differences.

The Construct of Social Dominance Orientation (SDO)

Sidanius et al. (2016, p. 152) define SDO as “the general desire to establish and maintain hierarchically structured intergroup relations regardless of the position of one's own group (s) within this hierarchy.” Since its first introduction in 1994 (Pratto et al. 1994), the SDO scale has gone through several iterations. The most recent version, the SDO7 (Ho et al. 2015), consists of 16 statements (such as “Some groups of people must be kept in their place”), which responders rate their levels of agreement with on 7-point Likert scales. Scores on these items can be averaged to form an SDO score (with half the items being reverse scored). Below we discuss the

dimensionality of SDO and how SDO relates to other variables and constructs.

Dimensionality

SDO was previously considered a unitary construct, but increasingly there is evidence that the construct can be divided into two: dominance (SDO-D) and egalitarianism (SDO-E) (Ho et al. 2012, 2015). SDO-D reflects preferences for active oppression of groups and is most reflective of hostile beliefs such as old-fashioned racism, dehumanization, and support for war (Sidanius et al. 2016). SDO-E, on the other hand, reflects a preference for inequality or at least an opposition to active measures toward reducing inequality. SDO-E is also often labeled “anti-egalitarianism.”

SDO-D and SDO-E have been shown to constitute separate facets of SDO in factor analyses, and they also differ when used as predictors for conceptually relevant variables. In the overview of relations between SDO and other traits below, we discuss correlations for full-scale SDO scores, while noting differences between SDO-D and SDO-E whenever relevant.

Predictive Power of SDO

SDT predicts that SDO will correlate positively with support for hierarchy-enhancing and negatively with hierarchy-attenuating ideologies or legitimizing myths. Consistent with this, SDO has been tied to support for a wide range of attitudes about ideology and politics, including political and, particularly, economic conservatism and support for social welfare and affirmative action (Sidanius and Pratto 1999). And SDO continues to predict emergent current phenomena, such as attitudes toward Syrian refugees and voting for Donald Trump (Dunwoody and McFarland 2018; Sheehy-Skeffington and Thomsen 2019). Most centrally, SDO has been found to consistently predict most kinds of prejudicial attitudes. This includes prejudice against women, the poor, ethnic/racial minorities, LGBTQ people, and immigrants (see Sidanius et al. 2016, for an overview of studies on this). Prejudicial attitudes predicted from having *low* scores on SDO are less studied, though there are indications that they could include prejudice against political conservatives

and against social groups deemed to be privileged (Lucas and Kteily 2018).

SDO has also been explored in relation to personality traits. In particular, SDO has been connected to many personality traits that are socially undesirable (Ho et al. 2015), such as the Dark Triad traits of Machiavellianism, narcissism, and psychopathy, which are particularly strongly linked to SDO-D. Relatedly, SDO-D in particular is inversely correlated with the honesty/humility dimension of the HEXACO personality inventory, which reflects an unwillingness to “get ahead” through dishonest means. Among the Big Five traits, SDO is most strongly related to agreeableness and openness to experience, with both correlations being negative here as well. The Empathic Concern scale is also negatively related to SDO (Lucas and Kteily 2018).

Distinctions Between SDO and Related Constructs

To further clarify what the SDO construct is meant to represent, we here go through three constructs that SDO is related to but importantly distinct from. These are interpersonal dominance, in-group favoritism, and right-wing authoritarianism.

Upon hearing the name “social dominance orientation,” a natural interpretation is that it reflects how oriented someone is toward being interpersonally dominant in social settings. But this is not what SDO is meant to measure, and the discriminant validity of SDO from standard personality measures of interpersonal dominance was established early on (Pratto et al. 1994; Sidanius and Pratto 1999): SDO concerns preferences regarding dominance hierarchies *between groups* in society, and so it is conceptually quite distinct from being interpersonally dominant.

Another misinterpretation of SDO is that it necessarily involves a preference that *one's own group* should be the one to dominate, so that it would correspond to in-group favoritism. Such an interpretation would indeed align with how SDO was originally conceptualized (e.g., Pratto et al. 1994), but contemporary understandings of SDO have shifted away from this to propose that SDO reflects a person's general orientation toward the

idea of hierarchies between groups. Consistent with SDT's prediction of *ideological asymmetry*, this suggests that a black American with a high score on SDO would not desire blacks to dominate whites, but would rather endorse the existing hierarchical status quo, even though this implies that whites continue to have more status and power than blacks (Ho et al. 2015; Sidanius and Pratto 1999). Accordingly, SDO is more positively associated with ethnic identity, perceived ethnic victimization, and other variables related to in-group favoritism among dominant than subordinate groups (Sidanius et al. 2016; Sidanius and Pratto 1999; Thomsen et al. 2010).

SDO is also related to, but yet distinct from, the concept of right-wing authoritarianism (RWA). RWA is manifested in submission to traditional authorities and in aggressive enforcement of established norms and customs. Thus, RWA and SDO are conceptually related, as they both concern attitudes toward hierarchy. Additionally, SDO and RWA tend to correlate quite substantially (usually at about $r = 0.40$), and they are both good predictors of many kinds of prejudicial attitudes.

However, SDO and RWA also have important theoretical and empirical distinctions. The dual-process motivational model of ideological attitudes (Duckitt and Sibley 2010) proposes that RWA reflects needs for social order and stable traditions, which result from seeing the world as a threatening and dangerous place. Thus, people high in RWA should prefer authorities that emphasize order and law and that defend traditional values. High SDO rather implies perceiving society as a competitive jungle, where you need to fight for power and control over others. People high in SDO therefore tend to prefer authorities that favor social inequality and group dominance.

While both RWA and SDO are associated with prejudice toward outgroups, the particular types of prejudice predicted from them are importantly different. According to Duckitt and Sibley (2010), RWA predicts dislike of groups that are socially deviant and/or norm-violating, whereas SDO predicts prejudice against groups that are low in status. For example, Thomsen et al. (2008) demonstrated in Switzerland and Southwestern USA

that for people high in RWA, negative attitudes toward immigrants were mainly provoked by immigrants' refusal to assimilate into the dominant culture and adhere to established norms, thus threatening cultural conventionality. In contrast, SDO predicted aggression toward immigrants that assimilated *too much* into the dominant culture and thus threatened the existing status boundaries.

SDO Is Contingent upon Hierarchical Position but Is also a Stable Trait

There are myriad studies documenting that SDO responds to the hierarchical nature of the context. Perhaps most importantly, it has been shown many times over that one's level of SDO is highly contingent on the placing of one's own group in the hierarchy. Consistent with how SDO only reflects self-interest when measured in dominant groups, people from lower-ranking groups tend to score substantially lower on SDO. For example, the difference in mean SDO between blacks and whites in the USA is substantial (e.g., Ho et al. 2015). It has been found that as the objective, salient, or perceived difference in power between groups becomes larger, so too does the difference in SDO levels between the groups (e.g., Levin 2004).

Consistent with this, in a meta-analysis across 27 countries, the average SDO level among dominant groups corresponded to the macrostructural level of inequality, that is, to the status gap between dominant and subordinates, consistent with dove-hawk type dynamics (Fischer et al. 2012). Accordingly, SDO among dominant groups also correlated across nations with macro-level indicators of poor governance, corruption, lack of rule of law, and democracy, all consistent with the notion that dominant groups are more likely to coercively claim resources the greater the macrostructural inequality. In an independent sample collected across 30 US states, macrostructural inequality (Gini) across states predicted SDO and mediated the effect of SDO on attitudes toward minorities (Kunst et al. 2017).

Just as SDT describes hierarchy-enhancing myths, it also describes hierarchy-enhancing social institutions. These are institutions which serve to uphold and enhance hierarchies, and

the theory predicts not only that people will self-select to hierarchy-enhancing versus hierarchy-attenuating institutions depending on their SDO levels but also that membership in hierarchy-enhancing institutions will lead to corresponding increases in SDO (Sidanius and Pratto 1999). Examples of institutions that have been described to have hierarchy-enhancing elements are the criminal justice system and the police force, housing, labor, healthcare, retail, and education (Sidanius and Pratto 1999).

Consistent with this, Sidanius et al. (1994) found that police officers in LA had higher mean SDO than students and jurors (who represented a random sample of Los Angeles citizens), whereas public defenders (working at the public defenders office, which is a HA institution) were found to be significantly less social dominance-oriented than both students and jurors.

SDO scores can also vary on more of a moment-to-moment basis when one's salient position in the hierarchical context changes. In a study illustrating this, Levin (1997) divided the SDO scale in half and put one half alongside questions about the tensions between Ashkenazi and Mizrahi Jews in Israel and the other half alongside questions about the tensions between Jews and Arabs. In the section on Jew conflict, Ashkenazis (who are seen as higher in status) scored higher on SDO than Mizrachis. But in the section on tensions between Jews and Arabs (where both groups of Jews are higher in status), then both groups of Jews scored higher than in the other condition, and the difference in scores between the groups disappeared.

Interestingly, Levin's (1997) study of contextual influences on SDO also illustrates how SDO also can be seen as a stable trait. Specifically, as has been shown in many studies, SDO has high rank-order stability. This means that people with relatively high scores in one context will be likely to be high scorers in other contexts. Despite the large shifts in mean SDO levels between conditions in Levin's study, correlations between SDO scores from the same participant were still substantial. Levin (2004) conceptually replicated these effects in Northern Ireland among Catholics and Protestants and further demonstrated that the

difference in SDO between dominant and subordinate groups are moderated by personal perception of the nature and size of the status gap.

Recently, Bratt et al. (2016) demonstrated the rank-order stability of SDO and its predictive power on outgroup prejudice over time using latent growth-curve modeling among large samples of Norwegian teenagers and American university students. Thomsen et al. (2010) demonstrated the stable relations of SDO scores across more than 3 years, as well as their longitudinal, cross-lagged effects on perceived white victimhood and prejudice. In summary, SDO does, contrary to the claims of some critics, constitute a *generalized* orientation toward intergroup hierarchy that holds *regardless* of which groups people are instructed to hold in mind when they fill out the SDO scale.

Interpretation of Low SDO Scores

SDO is often skewed toward the lower end of the scale. For instance, in Ho et al.'s (2015) validation study of the SDO7 scale, the average SDO score across six US samples on a 7-point Likert-scale was 2.6, corresponding to a percentage of maximum possible agreement (POMP) score of 27.2 (ranging from 0 to 100), including a representative population sample, the SDO mean of which was 3.0, corresponding to a POMP score of 32.5. Consistent with this, meta-analytical estimates indicated that the mean SDO POMP score across 27 nations was at 25.8, ranging from 15.7 in Switzerland to 63.0 in Japan (Fischer et al. 2012).

This raises issues about how scores are to be categorized. An SDO score of 3.8, for example, is below the scale midpoint of 4, yet it would place you about a standard deviation above the mean in Ho et al.'s samples. So, if you score at 3.8, do you then have high or low SDO? Are you predicted to want to attenuate or amplify hierarchies? Notably, SDO correlates very strongly with the anti-egalitarianism scale ($r = 0.85$ in Lucas and Kteily 2018), which has scores more evenly distributed around its scale midpoint than SDO has. Thus, it could be argued that SDO scores that are high relative to most sample means can be taken to represent opposition to egalitarianism, even if

they are below the midpoint of the scale (see Lucas and Kteily 2018). Plausibly, SDO scores might be shifted downward, e.g., through social desirability bias. If so, then the "true" SDO level of someone scoring 3.8 could be well above 4, and so they would have high SDO in both a relative and an absolute sense. Also, the low scores may simply reflect a general human aversion to strong group hierarchy or a preference for between-group equality, relatively speaking. Indeed, SDO scores would presumably only be shifted downward due to social desirability concerns if there is a widespread normative default expectation of equality (that makes endorsement of between-group dominance socially undesirable). Recent evidence from preverbal human infants suggests this is in fact the case, at least for default expectations of equal resource distribution (see Sheehy-Skeffington and Thomsen 2019).

In any case, although the majority of people may disagree with strong intergroup oppression in absolute terms, the variance between strongly and less strongly disagreeing with between-group hierarchy, as captured by the SDO scale, has proven one of the most robust predictors of intergroup phenomena in political psychology. Social dominance theory attempts to understand how this variance intersects with macrostructure and immediate institutional contexts and social roles to explain the continuous reproduction of the hierarchical status quo (Sidanius and Pratto 1999).

Evolution of Dominance and Egalitarianism

As we have seen, social dominance orientation predicts a plethora of political beliefs and ideologies. In the ethological literature, a concept known as *behavioral syndrome* captures traits that tend to correlate across situations and contexts. Given that SDO correlates with many related political beliefs, can these patterns be described as a behavioral syndrome?

Strategies of dominance and egalitarianism have deep evolutionary roots and can often coexist within the same species. In game theoretical

competitions for dominance, the contests often follow a hawk-dove dynamics where more formidable individuals (hawks) will prevail in such zero-sum conflicts, claiming contested resources, while subordinates (doves) will yield to more formidable opponents, so as to minimize costly fighting and injury. Consistent with the notion of evolved representations and motives for social dominance, greater physical formidability is also associated with greater dominance motives and claiming of societal resources among humans (Petersen et al. 2013). Indeed, even preverbal infants use cues of formidability and predict that the novel agents who are largest, most numerous and have won before will prevail in zero-sum conflict over smaller, less numerous, and previously weaker ones (Thomsen et al. 2011).

Importantly, egalitarian strategies are likely to have evolutionary underpinnings as well. In several primate species, coalitions form among lower-ranked males in order to gain access to fitness-relevant resources guarded by higher-ranking individuals. Furthermore, hunter-gatherers do display levelling mechanisms that keep any one individual from gaining despotic control (Boehm 1999).

If both dominant and egalitarian intergroup strategies, as tapped by low and high SDO, are maintained in human populations, what evolutionary genetic forces maintain them? A recent investigation using genetic sensitive data found that SDO and related political beliefs were all heritable and that the covariation between them are genetic in origin (Kleppestø et al. 2019).

It is possible, then, that both endorsement and opposition to intergroup hierarchies and the social policies that are meant to amplify or attenuate them build on universal adaptations for navigating social hierarchies. Given the enormous variation in available resources across ecological and social contexts throughout human history, it is unlikely that a single optimal level of hierarchy-preference exists. Hence, it is plausible that some kind of balancing selection may maintain the heritable variation in SDO, for example, through migration-selection balance, a process where genetic variation is maintained due to the changing selection pressures over time and space.

This maintenance of genetic variation can occur with personality traits because humans select environments and alliances that match their traits (niche-specialization or active gene-environment correlation). Individuals will then maximize the chance of obtaining fitness-relevant resources such as social alliances and mates.

The extensive evidence that people self-select to areas of study and professional careers that match their levels of SDO in terms of being hierarchy-enhancing or attenuating (e.g. people who are high in SDO are more likely to chose to become police officer and people low in SDO are more likely to chose to become social workers) and also stay longer and do better in these educations and jobs the better this SDO-institution match is (e.g. students with lower SDO get better grades in traditionally hierarchy-attenuating educations), and, finally, also socialize SDO to go up or down according to the hierarchy-enhancing or attenuating nature of the institution (Gatto and Dambrun 2012; Sidanius and Pratto 1999) provide support for this proposal. This also suggests that any heritability of SDO must be understood in its broadest sense to allow for such niche-building gene-environment associations, where SDO leads to the selection of environments that further adjust SDO levels in congruent ways.

Evolution of Sex Differences in Social Dominance Orientation

Across societies men score higher on SDO than women (Lee et al. 2011). Typically this difference is on the magnitude of about half a point on the scale (e.g., ~2.9 for men vs. ~2.5 for women in Ho et al. 2015). In contrast to the differences in scores between ethnic groups, which are thought to be entirely due to contextual factors, this sex difference is argued to be substantially less context dependent. This claim about stable gender differences on SDO is called the “invariance hypothesis” by SDO theoreticians and has been replicated across many cultures (Lee et al. 2011).

Why would the sexes differ in attitudes and behavior related to intergroup aggression? Sexual selection and parental investment theory suggest

that the payoff for costly intergroup aggression might be very different for men and women (Tooby and Cosmides 2010). In mammalian species, the fitness of males is constrained by access to fertile women. For women however, fitness payoffs are not constrained by the availability of fertile males, but rather by the time and resources required for successful gestation and lactation. This pattern gives rise to strong intrasexual competition among men for access to fertile females. This gives rise to men fighting other men individually, but also for *intergroup* competition where men raid, or attempt to dominate, other groups for access to the reproductive resources within them. Furthermore, coalitional aggression has also been observed in closely related primates (Wilson and Wrangham 2003).

Based on this, social dominance theory (Sidanius and Pratto 1999) predicted that intergroup conflict between socially constructed, arbitrary-set alliances (such as race, ethnicity, culture, class, caste, religion) will be a primarily male-on-male phenomena. This implies that the main targets of intergroup oppression will be subordinate males (i.e., in an American context black and Hispanic males; in a European context Muslim/Middle Eastern and African males), and so SDT coined this idea the *subordinate male target hypothesis (SMTH)* (Sidanius and Pratto 1999), described more generally elsewhere as the *male warrior hypothesis* (McDonald et al. 2012). It postulates that men engage in coalitional aggression for direct sexual access but also indirectly for foraging territories, social influence, power, and status, and it may explain why men are much more likely to be both perpetrators and victims of intergroup violence and why men tend to be less egalitarian in their social attitudes, such as SDO.

Indeed, the available evidence strongly suggest that men are more prejudiced, conservative, punitive, and racist than women are (Sidanius and Pratto 1999). Nevertheless, modern expressions of prejudice are probably not adaptations in and of themselves (Navarrete et al. 2010). However, they might have important evolutionary underpinnings, such as the alliance detection system. That is, modern prejudice might be expressions of psychological adaptations that evolved in a context where coalitional aggression was much more

common than it is today (Tooby and Cosmides 2010). Indeed, high degrees of coalitional aggression can be observed among current hunter-gatherer tribes.

SDT argues that men are not just the primary agents of discrimination based on arbitrary-set group differences (such as race), but also the main target of it (Sidanius and Pratto 1999). Experimental psychophysiological evidence on prepared fear-learning supports the proposition that we tend to primarily be wary of outgroup males, rather than females (Navarrete et al. 2009). For women the argument has been made that such outgroup bias is primarily motivated by fear of sexual coercion, while for males it is based on motives for aggression and social dominance (Navarrete et al. 2010). In other words, sex is an important variable in both the amount of prejudice held by individuals but also in who is targeted for discrimination.

Another crucial part of the male warrior hypothesis is that it predicts variation among males in their desire to dominate other groups. That is, men are expected to calibrate their desire for dominance based on their own formidability, leadership ability, available alliances, and other environmental information (Petersen et al. 2013). In fact, the association between physical formidability and SDO holds even when controlling for the time spent lifting weights, suggesting that physical formidability directly drives SDO, rather than the reverse (Price et al. 2017; Sheehy-Skeffington and Thomsen 2019).

Conclusion

Human societies tend to be structured as hierarchies where dominant groups enjoy a greater access to fitness-relevant resources. Social dominance orientation (SDO) measures the degree to which individuals prefer that dominant groups stay on top, or if society should be structured in a more egalitarian fashion. SDO predicts many important attitudes, such as political beliefs, prejudice, and life choices. Men tend to score higher, which might reflect men's sexually selected tendency to be motivated to engage in intrasexual competition for social status, which in turn give

them access to fertile females. Humans are likely to possess adaptations designed for both dominance and egalitarianism.

Social Dominance Reduces Fighting

Isaac Ligocki

Synonyms

Loser effects; Resource holding potential; Winner effects

Definition

In certain circumstances, the establishment of dominance relationships may reduce the frequency or intensity of agonistic interactions between individuals within the hierarchy.

Introduction

Dominance relationships within groups typically revolve around access to resources such as food, shelter, and mating opportunities. More dominant individuals typically have greater access to these resources. In many cases, once established, dominance relationships enable individuals with differing dominance status to coexist relatively peacefully without the need for repeated agonistic encounters. While the extent to which conflict is reduced depends on the system and the context of conflict, familiarity with conspecifics does often seem to correlate with reduced aggression.

Conflict and Dominance

Across animal taxa, organisms engage in conflict with one another for resources such as food, shelter, and mates. Success in such conflict is often attributed to resource holding potential (RHP), such that individuals better equipped to acquire and maintain resources have greater access to them (Parker 1974). Conflict between individuals in social groups is often greatest between individuals near one another in size or status which have similar RHP; however in many cases even small size discrepancies can be adequate to predict the outcome of conflict. Conflict can be costly for individuals, and thus mechanisms which serve to establish dominance relationships without physical altercations could be selectively advantageous if it reduces the costs associated with agonistic interactions (Smith and Price 1973).

Dominance relationships have been an important focus of behavioral research in both human and nonhuman animals for quite some time. Selection for dominance hierarchies has been proposed as a possible mechanism

through which perpetual aggressive encounters can be reduced or avoided, although whether this mechanism exists has been questioned and may vary between species and populations. Support for this selective advantage of dominance relationships has been suggested in alpine ibex, *Capra ibex*. Male ibex compete with one another for access to mates; however actual conflict during the rut appears to be lessened through dominance relationships which were established prior to the breeding season (Willisch and Neuhaus 2010). Similarly, for great bustard, *Otis tarda*, dominance status is associated with reduced conflict once it's been established, at least for high-ranking individuals (Magaña et al. 2011).

Often physical features such as size, ornaments, or auditory cues provide honest information about the resource holding potential of individuals. So long as these traits are honest signals of quality, dominance hierarchies within groups may form as a result of these cues in the absence of actual agonistic interactions. While aggression may be reduced in systems with cues, period aggression or "testing" of individuals may be important for maintaining the honesty of the signal and prevent the evolution of cheaters in the system. Indeed, individuals with traits that have been experimentally modified often face severe aggression from conspecifics (Tibbetts 2004). Interestingly, in pukeko (*Porphyrio porphyrio melanotus*), there appears to be feedback between agonistic interactions resulting from experimentally modified cues and the actual trait value (size of a "shield" on their head in this case) of the cue (Dey et al. 2014) such that individuals whose shields were experimentally reduced faced aggression as though they were lower rank and their actual shield size reduced as well.

Winner effects, loser effects, and bystander effects have been proposed as possible mechanisms that explain the dominance relationships emerging from agonistic conflict. Winner effects (individuals being more likely to win subsequent bouts after winning previous encounters) and loser effects (individuals being more likely to lose subsequent bouts following losses in previous encounters) may have important

consequences for emergent social structure, although evidence for each effect varies from system to system. In the green anole, *Anolis carolinensis*, both winner and loser effects may be at least in part moderated through neuroendocrine pathways (Greenberg and Crews 1990). Bystander effects emerge when individuals observe interactions between conspecifics and decide whether and who to engage in agonistic encounters depending on the outcome of the initial conflict (Earley 2010) and further reduce the need for direct conflict to resolve dominance relationships.

One mechanism through which dominance relationships may facilitate reduced aggression is through policing. In many animal societies, the presence of particular group members is associated with reduced conflict in groups, as well as shifts in other group characteristics. In many cases, these "policers" are relatively high-ranking individuals which possess the power to influence group dynamics. In human societies, policing (specifically law enforcement) may similarly reinforce cooperation between individuals (Kümmerli 2011).

Conclusions

In many cases dominance relationships may lead to reduced aggression between individuals and thus reduce risks associated with injury through agonistic encounters. Possible mechanisms through which agonistic interactions could be reduced include familiarity with social partners or honest signals of quality or resource holding potential. Additionally, in many human and non-human animal societies alike, policing (often by high-ranking individuals) may further reduce conflict and facilitate for cooperative interactions between individuals.

Definition

The act of engaging in a social behavior that is beneficial to another individual with the

expectation of a reward in return that outweighs the costs associated with the behavior.

Introduction

Social interactions are among the most fundamental characteristics of human existence. Human beings have lived and interacted in social groups throughout our evolutionary history. Homans (1958) was one of the first scholars to conceptualize social interactions as exchanges between two or more people that have both costs and rewards. Building on this conceptualization, social exchange theory posits that individuals engage in a particular social behavior only if the rewards outweigh the costs.

Social exchange theory is a helpful framework in understanding prosocial behavior, actions performed with the intention of benefiting another individual or group. Social exchange theory argues that one engages in prosocial behavior only if they anticipate higher rewards (e.g., receiving reciprocal help in the future) than costs (e.g., the time associated with help). In a related vein, social exchange is also linked to cooperation, which is integral in ensuring group living. Cooperation inherently brings costs, but when those costs are outweighed by rewards, individuals cooperate and potentially reach benefits they cannot achieve on their own. Cooperation is seen in other animals too (e.g., insects, fish, birds, mammals). Yet this cooperation is typically undertaken with other conspecifics with whom the individual shares genes. Indeed, helping and receiving help from relatives offer adaptive advantage (e.g., work on kin selection and inclusive fitness, see Hamilton 1964). What is unique about human cooperation is that human beings have the capacity to cooperate widely with other conspecifics even when they do not share any genetic material. This ability to cooperate with non-kin on a large scale has been possible thanks to the cognitive skill of engaging in social exchange, and this has ultimately enabled human beings to form cohesive, structured, and efficient groups and build the civilization we have today.

Social Exchange Among Non-kin

Social exchange can take place between two or more individuals in a variety of social settings that do not include kin relationships. Romantic relationships (that may or may not involve producing offspring), friendships, neighbor relationships, colloquial relationships, and business partnerships are common examples. Social exchange can even take place between individuals who do not know each other prior to the exchange.

Such exchanges, however, are known to be less stable than kin relationships as they have a voluntary nature. In such situations, the conditions of the exchange are more likely to be explicit and rely on agreed upon norms (e.g., social contracts; Cosmides and Tooby 1992). Such social exchange requires a highly evolved cognitive capacity that involves perceiving the interaction partner's mental state and intention and calculation of costs and rewards and detecting potential deceit. Hence, social exchange can be mentally taxing. Moreover, it is risky considering selection may favor cheaters who receive help without offering the rewards. Therefore, researchers have posited that human beings have developed sophisticated cognitive mechanisms to detect and exclude cheaters and low-value group members from the social exchange circle (Cosmides and Tooby 1992). Neurobiological evidence supports this; deceit detection has been identified to be executed by specific regions in the brain (i.e., orbitofrontal cortex, temporal pole, and amygdala; Stone et al. 2002).

Reciprocal altruism is central to social exchange among non-kin. Reciprocal altruism (Trivers 1971) refers to engaging in a costly prosocial act when the individual expects that it will be similarly reciprocated in the future. In this framework, the immediate cost of helping is outweighed by the future reward of being reciprocated when one needs help. Such social exchange typically involves *positive* reciprocity, where individual expects a benefit in return of a benefit, but social exchange may also be characterized by *negative* reciprocity, where individual offers help, or halts aggression, in hopes that the other individual will not harm

them in the future. In both cases, over time, both members of the reciprocal relationship will be better off as compared to their initial state. Reciprocal altruism can lead to successful and stable cooperation in social groups that interact frequently with each other and have formed trust based on prior affirmative social exchanges. Probably to ensure this, human beings have strong needs to maintain trust and good social reputation and avoid social exclusion from one's social network (e.g., Panchanathan and Boyd 2004). In addition, social norms sanctioning the punishment of cheaters by cooperators protect the secure environment to ensure that reciprocity is sustainable (e.g., Bornstein and Weisel 2010).

Social exchange among non-kin is argued to have evolved as an adaptation to combat resource scarcity and unpredictability, which characterized our evolutionary history. It is argued that the variability in available resources was combatted with an "insurance" mechanism: "Successful" individuals who have high resources at a given point in time agree to share these resources with the less successful individuals in exchange for receiving their resources when they cannot secure their own in the future. This strategy ensures that the total access to resources of all individuals shows less variability in unpredictable settings (Kaplan et al. 2000). Recent support for this conjecture comes from a study where participants in a virtual setting readily established reciprocal trading relationships in face of unsynchronized variance in resources and hence maximized the average resources each individual has at any given time point (Kaplan et al. 2012).

Conclusion

Social exchange is a crucial mechanism through which individuals judge the costs and benefits of a social interaction and decide whether to engage in it or not. Thanks to this sophisticated cognitive ability, human beings have been able to cooperate with non-kin and form large-scale social groups, which have been the engine of modern life.

In environments characterized by mutual trust and respect for the social norms, social exchange can aid in the advancement of both the individual and the social group.

Social Exchange Theory

Janine Bosak

Dublin City University, Dublin, Ireland

Definition

A broad conceptual paradigm that aims to predict how social interactions and relationships are built, maintained, and ended.

Introduction

Social exchange theory refers to a broad conceptual paradigm for understanding social interaction, which can be found in a number of social science disciplines including, for example, social psychology, anthropology, management, and sociology. It is therefore not a single theory of social exchange (Barbalet 2017) but can be better thought of as a family of conceptual models (Cropanzano et al. 2017; Cropanzano and Mitchell 2005). These conceptual models aim to predict how social interactions and relationships are built, maintained, and ended (Agnew and Lehmiller 2007). According to social exchange theories, social life involves a series of sequential interactions between two or more parties (individuals or institutions), in which resources, material and nonmaterial, are exchanged (Homans 1958). Over time, these interdependent, reciprocal exchanges have the potential to foster high-quality relationships characterized by loyalty, trust, and mutual commitments.

Background and Principles of Social Exchange Theory

The foundational work for social exchange theory can be found in the writings of scholars like George Homans (1958, 1961), Peter Blau (1964), John Thibaut and Harold Kelley (1959), and Richard Emerson (1962). Homans (1958) conceptualized social behavior as an exchange of activity between

at least two people, which is more or less rewarding or costly. A behavior by one party elicits a reaction in the other party that “either reinforces the original action and therefore encourages its repetition or through punishment dissuades its recurrence” (Barbalet 2017, p. 1). Principles of operant conditioning in behaviorism thus underlie Homan’s approach to social exchange. In contrast, Blau’s (1964) approach builds on neoclassical economic theory and adapts a utilitarian view of human behavior. In his micro-exchange theory, Blau also believes social exchange to be a fundamental process in social life and considers the costs and benefits that accompany a person’s interaction. However, according to Blau’s (1964) utilitarian view, social exchange is characterized by voluntary acts of individuals that are motivated by the returns they are believed to bring. Moreover, albeit rewards might reinforce the behavior of individuals in social exchanges, Blau believes the process of reinforcement to be insufficient to explain the relation that develops between the interacting individuals. He therefore focuses on the emergent properties in interpersonal relations that arise from the reciprocal exchange of benefits between the participants.

Building on this early work different perspectives on social exchange have evolved over the years. These different perspectives, however, share some common features and guiding principles (see Cropanzano and Mitchell 2005): (1) exchange rules; (2) resources exchanged; and (3) interpersonal relationships. First, *exchange rules* reflect the guidelines of exchange processes and guide the behavior of the involved parties. Most research emphasizes the rule of reciprocity, albeit other rules are also relevant for understanding social interaction and exchange relationships. Reciprocity implies repayment in kind such that a positive treatment by one party is reciprocated by the other. While a positive norm of reciprocity has attracted the most attention by far, a negative reciprocity norm can also shape people’s behavior in exchange processes (Cropanzano and Mitchell 2007). For example, experienced harm by one party might be reciprocated. In addition, experienced workplace incivility was found to facilitate

interpersonal deviance, particularly for individuals who were high in both hostile attribution bias and negative reciprocity beliefs (Wu et al. 2014). Some scholars assert that reciprocity is a tendency that is learned by people through the process of socialization, whereas others argue that it is driven by evolutionary considerations and facilitated by cognitive adaptations (e.g., Cosmides and Tooby 2005). In general, it appears that the norm of reciprocity is a universal principle, although the degree with which this principle is applied by individuals and cultures differs. Depending on whether individuals endorse the norm of reciprocity more or less, they are referred to as higher or lower on exchange ideology. For example, in their longitudinal study of conscripts to military service, Pazy and Ganzach (2010) found perceived pre-entry organizational support was positively related to combat choice service, particularly so for conscripts high in exchange ideology. While most research emphasizes reciprocal exchanges that do not require explicit bargaining, other forms such as negotiated agreements do exist (Cropanzano and Mitchell 2007). Negotiated exchanges tend to be more explicit and *quid pro quo*, they are often part of economic transactions and thus less likely to contribute to closer relationships, and they may or may not imply legal or contractual sanctions.

Second, *exchange resources* refer to the types of resources and potential benefits in exchange processes. These are typically classified into economic and socioemotional resources (Cropanzano and Mitchell 2005). Economic resources are commonly tangible and meet the individual's financial needs (e.g., money, goods, etc.). In contrast, socioeconomic resources are commonly not tangible and yield symbolic value (e.g., loyalty, love, etc.). The receipt of socioeconomic benefits further conveys the message to its beneficiary that he/she is valued and respected.

Finally, a common feature of social exchange theories is the focus on the development of *social exchange relationships*. The focus on interpersonal connections is particularly relevant to the study of workplace relationships in management and

organization science. According to Blau (1964), individuals either engage in economic exchange or social exchange with other parties. Economic exchange relationships entail clearly specified benefits of short-term financial and material nature, whereas social exchange relationships are characterized by unspecified obligations of socioemotional nature. Social exchange relations, thus, bear a greater risk that a favor demonstrated by one party is not returned and therefore require a certain level of trust at the beginning. Over time, mutually benefiting reciprocal exchanges foster positive, enduring relationships characterized by loyalty, trust, and commitment, whereas economic exchange relations do not. For example, employees who perceive their employers providing organizational support and caring about them, reciprocate with more positive work attitudes (e.g., commitment) and higher levels of extra-role performance.

Conclusion

Social exchange theory has emerged as one of the most prominent theoretical perspectives for understanding social interactions and relationships in the field of social sciences. It has become an integral part of theories such as psychological contracts, organizational justice, organizational support, and leader-member exchange, and social networks. Nevertheless, social exchange theory has its limitations. Individual self-interest, for example, is not the only possible reason for social exchange; other exchange rules do exist (e.g., altruism, competition) but have been less researched. In addition, social exchange is rarely an isolated event but rather implies a multitude of social exchanges in which actors are engaged simultaneously (Barbarlet 2017). Most recently, scholars have also criticized the lack of sufficient theoretical precision (e.g., overlapping constructs), which might undermine the utility of social exchange theory (Cropanzano et al. 2017). Social exchange theory, however, remains a powerful conceptual framework that explains how reciprocal transactions foster and maintain social relationships and – when mutually beneficial for

the involved parties – contribute toward high-quality relationships over time.

Synonyms

Group organization; Social rank; Social status;
Social structure; Status hierarchy

Definition

Social groups often are organized hierarchically, such that higher-ranking group members have greater control over valued group resources than other group members. Higher-ranking individuals also enjoy relatively more freedom to act in accordance with their own goals and desires and have greater capacity to exert their will over lower-ranking group members. Ultimately, these proximate advantages yield fitness benefits for high-ranking individuals and their offspring and help lower-ranking group members by allowing them to benefit from the increased overall prosperity of the group.

Introduction

Across many group-living species, to include primates, social hierarchies exist in which high-ranking individuals control a disproportionate amount of resources and influence in the group (Maner and Case 2016). The ubiquity of hierarchy among social species is likely due to its evolutionary benefits for both the individual and, potentially, the group (Maner and Case 2016; Van Vugt 2006). These individual- and group-level benefits are theorized to have perpetuated the existence of hierarchically arranged groups throughout evolutionary history. The study of humans and nonhuman animals has revealed some functionally specific behavioral and

psychological capacities that facilitate individuals' ability to navigate social hierarchies (Cheng et al. 2013). Other work has identified some of the key fitness benefits experienced by groups with hierarchical structures (Powers and Lehmann 2014; Van Vugt 2006). Together, these complimentary streams of research provide compelling evidence for the evolutionary advantage of social hierarchy.

Individual-Level Fitness Benefits of Social Hierarchy

Social hierarchies provide ample opportunities for individuals to accrue both direct and indirect fitness benefits. Regarding direct benefits, high-ranking individuals tend to receive specific perks unavailable to those lower in the hierarchy, such as a disproportionately large share of a group-produced good (von Rueden and van Vugt 2015). Importantly, these benefits come to high-ranking individuals without resistance from lower-ranking group members. That is, high-ranking individuals do not have to continuously achieve their rank on a case-by-case basis, but rather, their reputation remains stable over time within the group thus affording the accumulation of fitness benefits (Henrich and Gil-White 2001).

Beyond receiving additional benefits, high-ranking individuals also are subject to fewer constraints than low-ranking group members. For example, high-ranking members in certain small-scale societies sometimes have rights to polygyny that low-ranking members do not (von Rueden and van Vugt 2015). This combination of increased access to fitness-enhancing resources and decreased social constraints provide high-ranking individuals with easier routes to evolutionary success than their low-ranking counterparts.

In addition to the direct benefits awarded to high-ranking individuals, they are awarded indirect benefits as well. Specifically, high-ranking individuals receive higher social status, represented by things such as deference from lower-ranking group members and increased

mate value, ultimately leading to tangible fitness advantages. Specifically, von Rueden and van Vugt (2015) found that social status in small-scale societies was positively associated with reproductive success. Notably, this association remains when material resources are equal between high- and low-ranking individuals. For example, among the Tsimane of Bolivia, leaders of fishing excursions do not take more fish than others, but they do enjoy greater reproductive success and social support than lower-ranking individuals (Glowacki and von Rueden 2015).

Dominance and Prestige: Two Evolved Mechanisms to Navigate Social Hierarchies

Because social hierarchies have been a prominent feature of many social groups throughout evolutionary history and provide immense opportunity for fitness benefits, many species possess behavioral repertoires designed to successfully navigate social hierarchies. Scholars have classified these behavioral repertoires into two categories: a socially coercive strategy in which higher rank is acquired through actual or threatened aggression – the dominance strategy – and a more pro-social strategy – the prestige strategy – in which elevated social standing is achieved by demonstrating group-valued skills and expertise.

One key difference between the dominance- and prestige-based strategies is the route through which deference is conferred. Individuals who employ the dominance strategy use aggression and intimidation to demand deference from subordinates (Cheng et al. 2013). Importantly, their tactics can often be more subtle than direct physical aggression, such as manipulating control of a valuable resource. For example, dominant leaders have been observed to monopolize control over resources such as useful information and access to valuable social partners (Maner and Case 2016). Through anti-social means such as these, dominant individuals are able to establish and protect their high-ranking positions and, as such, are able to reap the fitness benefits associated with those positions.

In contrast to the dominance strategy is the prestige strategy – another viable route through which individuals can navigate their group's hierarchy. The prestige strategy involves receiving freely conferred deference from subordinates by demonstrating one's worth to the group (Henrich and Gil-White 2001; Maner and Case 2016). In essence, subordinates trade their deference for access to the prestigious individual with the goal of learning his or her valuable skills. Prestige is a strategy primarily observed in humans that requires advanced cognitive abilities such as ranking the skills of others and preferentially copying those who rank highest. These learning capacities allow prestigious individuals to maintain high social rank well past their physical primes, as evidenced by the high status of the elderly that is much more common in humans than in other species. Crucially, it is not enough to have valuable skills and abilities; leaders must also be willing to share their expertise with the group to garner prestige (Sugiyama and Sugiyama 2003). Thus, prestigious leaders help the group by acting as a model for others to follow.

Furthermore, prestigious individuals differ from dominants in how they obtain and maintain influence over others. Prestigious individuals' opinions are given great consideration and typically are followed, but deference is not required as it is for dominants. For instance, among the Nyangatom, a nomadic group in East Africa, unresolved conflicts can be presented to the council of elders for mediation. Although their word is not binding, to not follow it would likely result in social consequences from other group members, such as exclusion from group activities (Glowacki and von Rueden 2015). By garnering rewards through prosocial behaviors that benefit the group, prestigious individuals procure a fitness advantage over lower-ranking individuals.

Group-Level Fitness Benefits

Given the numerous fitness advantages enjoyed by those with high social rank, why do some group members choose to follow? Throughout phylogenetic history, between-group

selection pressures, such as intergroup conflict, were sometimes stronger than within-group selection pressures. As such, groups that could collectively work together to produce the best outcomes for the entire group had an advantage over groups that were unable to coordinate their actions (Van Vugt 2006).

Hierarchically structured groups are best able to act collectively to reach a common goal that benefits everyone (Glowacki and von Rueden 2015). Indeed, even in egalitarian groups, task-based hierarchies sometimes emerge to facilitate collective action for a common good (e.g., Powers and Lehmann 2014). One of the key reasons collective action can fail is because group members known as “free-riders” enjoy the common good without themselves contributing to its production. Because punishing and deterring free-riding is one of the primary functions served by high-ranking group members (Lukaszewski et al. 2016), hierarchically arranged groups historically were more efficient than egalitarian groups at carrying out the types of collective action required to outcompete intergroup rivals.

Because hierarchically structured groups can outcompete groups with more egalitarian structures, individual members of those hierarchical groups tend to personally prosper – they enjoy elevated resource potential and reproductive success. This is one reason social hierarchy can become cemented into a group (Powers and Lehmann 2014). Moreover, because members of groups become dependent on the common good produced by hierarchical groups, they tend to remain in those groups, even when they themselves hold a lower-ranking (and less desirable) position within the group’s hierarchy (Powers and Lehmann 2014). Thus, by increasing the productivity of the group as well as group members’ dependence on the group, social hierarchy can create powerful, cohesive groups that are better equipped to survive than egalitarian groups.

As well as being better equipped to survive at their current size, groups that are organized hierarchically also are better equipped to expand in number compared to egalitarian groups. After

the advent of agriculture, human groups grew in size in response to the increase in available resources but, simultaneously, those resources became more easily monopolized than ever before, leading to increased intragroup competition and free-riding. Because egalitarian groups are less equipped than hierarchically arranged groups to discourage free-riding, groups without social hierarchy had an especially difficult time maintaining their prosperity. In contrast, groups with stringent social hierarchies experienced unprecedented levels of cooperation and coordination, allowing them to expand even further in size (Richerson and Boyd 1999).

Conclusion

Compared to more egalitarian social structures, social hierarchies provide greater opportunities for group-level fitness advantages through leader-follower dynamics that promote collective action and conflict resolution. Nonetheless, not all group members benefit equally from social hierarchy due to the stark contrast in individual-level fitness advantages at different levels of the hierarchy. To capitalize on hierarchically arranged groups, humans and other social organisms employ functional strategies, namely, dominance and prestige, to help them successfully navigate those hierarchies, ultimately maximizing their ability to survive and reproduce. Due to the evolutionary benefits available to members of hierarchically structured groups, it is no surprise that social hierarchy has pervaded almost every human society.

Social Hypotheses of Homophobia

Alexandra Zapko-Willmes¹ and
Christian Kandler²

Synonyms

Homonegativity; Sexual prejudice

Definition

An umbrella term for a negative (attitudinal, affective, or behavioral) response towards homosexuality and homosexuals.

Introduction

Following societal change in thinking about the status of homosexuality and its politically motivated removal from the *Diagnostic and Statistical Manual of Mental Disorders* in 1974, research on the origin of homosexuality declined and was replaced by studies on homophobia. The term

homophobia, defined as “the dread of being in close quarters with homosexuals – and in the case of homosexuals themselves, self-loathing” (Weinberg 1972, p. 4), has been repeatedly criticized for its inherent evaluation of the response as (fundamentally) fear-based, pathological, irrational, and even unscientific (e.g., O'Donohue and Caselles 1993). As a consequence, a variety of broad and narrow re-definitions of the term as well as alternative terms, among others, *homonegativity*, *homosexism*, and *sexual prejudice*, (Herek and McLemore 2013; O'Donohue and Caselles 1993), emerged. Accompanied by several theoretically and methodologically diverging measures, this conglomeration of neologisms for the same, a fraction of the same, or a similar construct has been impeded the investigation of homophobia and its underlying mechanisms because of questionable validity of comparisons across studies. Nonetheless, several socially rooted factors associated with negative responses (of heterosexuals) towards homosexuality and homosexuals in the Western civilization could be repeatedly and robustly identified, allowing for the following formulation of social hypotheses of homophobia.

Religiosity, Fundamentalism, and Right-Wing Authoritarianism

A majority of studies, mostly relying on occidental samples, found a positive association between (Christian) religiosity and homophobia, which has been also reported for Muslims (e.g., Anderson and Koc 2015). Herek and McLemore (2013) interpreted this correlation in terms of three psychological functions: (1) The maintenance and strengthening of one's religious identity, which relies on a specific value system and moral conviction; (2) the reinforcement of the affiliation with one's religious group; and (3) the countering of one's experienced insecurities by (re-)affirming one's compliance with normative order due to an “unequivocal obedience to religious authority, strict conformity to religious teachings, feelings of moral superiority over outgroups, and self-righteousness” (i.e., fundamentalism; p. 10).

Especially the latter two functions might have been phylogenetically advantageous, since they enhance ingroup cohesion, which might have been critical for the group's survival.

However, these functions neither apply to every highly religious heterosexual person nor is every highly religious person invariably homophobic. On the contrary, several findings suggest that some highly religious individuals accept homosexuals (e.g., Hunsberger and Jackson 2005). These individual differences may be attributable to right-wing authoritarianism (RWA), a personality characteristic found to be positively associated with both homophobia and religious fundamentalism (Altemeyer and Hunsberger 1992). RWA is characterized by allegiance to established authorities, antagonism towards societal minorities, and conformity with conservative values and traditions. It has been argued that highly authoritarian individuals, who also tend to be religiously fundamentalist, condemn any form of nonconformist, non-heteronormative life style as a consequence of their vehement advocacy of conservatism and traditionalism, resulting in homophobic tendencies (Nagoshi et al. 2008). Yet, the correlation between religiosity and homophobia has been found to persist even when controlling for RWA (Johnson et al. 2011), supporting an association between religiosity and homophobia independent of authoritarian tendencies. In summary, previous and current research suggests that homophobia is positively associated with rudimental beliefs and social attitudes including religiosity (hypothesis 1), fundamentalism (hypothesis 2), and right-wing authoritarianism (hypothesis 3).

Gender, Gender Role, and Masculinity

Men have been consistently observed to be more homophobic than women and to hold more negative attitudes towards homosexual men than homosexual women (Herek and McLemore 2013). This gender difference and the differentiation regarding the homosexual's gender have been argued to be created as a consequence of the sociocultural pressure of adhering to a specific

gender role. While women also face gender role expectations, men are confronted with more (ingroup-)dynamic, inflexible, and sensitive societal ideals of masculinity that have to be proven on a regular basis in order to achieve acceptance by other male heterosexuals (Herek and McLemore 2013). Consequences of failing the expression of masculinity are, among others, being labeled homosexual (e.g., Bosson and Vandello 2011) and aggressive behavior against oneself (e.g., Parrott 2009). As Herek and McLemore (2013) put it, “sexual prejudice is often a strategy for men to demonstrate—both to others and themselves—their ability to meet cultural expectations about masculinity” (p. 14).

From an evolutionary psychological point of view, expressing one’s masculinity might have been fruitful for attracting potential mating partners, because aggressively demonstrated strength and superiority over (apparently) physically weaker males might have appeared as an improvement of the individual fitness and, thus, the chances of the offspring’s survival. In other words, natural selection might have contributed to the continuance of homophobia (see ► [Genetic Hypotheses of Homophobia](#)). In summary, research suggests three further hypotheses: In face of different social role expectations, Heterosexual men display more homophobic responses than heterosexual women (hypothesis 4), hold more negative attitudes towards homosexual men than towards homosexual women (hypothesis 5), and would show more homophobic responses if their masculinity is threatened (hypothesis 6).

Are Heterosexual Homophobes Secretly Attracted to Homosexuals?

Research on the popular belief that male heterosexual homophobes are as a matter of fact closet-homosexuals who either try to conceal their own and true sexual attraction towards men or use such an attitudinal stance as a solution for an inner conflict with their world view (i.e., as a defensive reaction, see above) remains inconclusive (Herek and McLemore 2013). As

Herek and McLemore pointed out, although several studies apparently showed same-sex attraction in self-proclaimed homophobic heterosexual men, this interpretation is debatable due to methodological limitations. While it cannot be fully excluded that homophobia also serves as a defensive function for some undisclosed homosexual men, current research generally does not support this notion.

Homophobia as a Culturally Driven Phenomenon?

Herek and McLemore propose that homophobia is a cultural rather than a primarily psychologically established phenomenon. According to them, cultural institutions, for example religious denominations, uphold a (self-defining) homophobic doctrine. Along with political and juridical decisions, these cultural institutions define and structure the social environment in which the individual is placed. They distribute power and status among groups, subsequently specifying more and less desirable group affiliations. The individual naturally strives for the satisfaction of critical psychological needs (see above) as well as an opportune group affiliation, which culminates in the internalization of the externalized stigma. The political development in the Western society in the last 40 years proves this account to be somewhat accurate, as can be observed in decreased criminal offenses against homosexuals and the overall more favorable opinion towards homosexuality.

This might be partly explained by Allport’s (1954) Intergroup Contact Theory, which states that positive intergroup contact can diminish prejudice. Through the change in the societal perception of homosexuals, the subsequent inclusion of homosexuals in the “inner circle,” and the increase of the salience of homosexuals in everyday situations and selective institutions (e.g., student clubs representing homosexuals), the higher probability of a positive (less stigmatized) contact with homosexuals might lead to an additional decrease in homophobia. The contact hypothesis has been supported for antigay attitudes (e.g.,

Herek and Capitanio 1996). In other words, positive contact with homosexuals is correlated with a decrease in homophobic tendencies in heterosexuals (hypothesis 7).

Still, the development towards more political correctness and a heightened chance in positive contact with homosexuals does not cover latent signs of homophobic tendencies like the ongoing pejorative use of homosexuality or the prevalent stigmatization of homosexuals in sports, which alludes to an underlying, more visceral, and phylogenetic aspect of homophobia beyond a mere cultural stigma.

Conclusion

To sum up, homophobia remains a multifaceted, complex phenomenon, rooted both in cultural, social, evolutionary, and differential psychological mechanisms. Although current research suggests that religiosity, religious fundamentalism, authoritarianism, male gender role expectations, and masculinity play a major role in the development of homophobia and that sociocultural acceptance of homosexuals as well as positive contact are associated with less homophobia, measures beyond self-rated attitudes towards homosexuality or homosexuals have to be developed to measure homophobia (e.g., implicit measures) more objectively and accurately (i.e., to control for socially desirable responding) to fully grasp the sources of homophobia. Moreover, research on homophobia has to further expand to non-Western societies in order to distinguish religious from cultural influences on homophobia and clarify the function(s) of homophobia. A distinct and elaborate definition of homophobia is necessary, especially for the better understanding of the link between negative attitudinal, affective, and behavioral responses towards homosexuality and homosexuals. It is only by finding an enlightened and globally functional conceptualization that discrimination of sexual minorities like homosexuals can be fully understood and diminished on an international level.

Definition

The social intelligence hypothesis is a scientific hypothesis proposing that social complexity was the main selective force shaping the evolution of sophisticated intelligence and large brains in extant animals.

Introduction

The social intelligence hypothesis (SIH) is a popular hypothesis that purports to explain the evolution of large brains and sophisticated cognitive abilities. The SIH proposes that social complexity is cognitively demanding and is thus the key selective pressure affecting brain size and, by extension, intelligence (Dunbar 1998; Humphrey 1976; Jolly 1966). The SIH was originally developed to explain the large brains and intelligent behavior of primates compared to other animals (Dunbar 1998). It has also found support across many mammal and bird species to explain variation in both brain size and cognitive abilities (Dunbar and Shultz 2007; Shultz and Dunbar 2010). Though often pitted against “ecological” hypotheses, which emphasize the role of diet and environmental challenges in brain evolution, proponents of the SIH often claim that the two are not mutually exclusive. Instead, they propose that ecological problems are solved socially, not individually, and that ecological selection thus acts indirectly on brain size through selection for social intelligence (Dunbar and Shultz 2007). More conservative forms of the SIH simply posit that more complex social groups favor specialized social cognition. But ultimately, the SIH suggests that the primary function of intelligence is in the social domain.

Origins of the SIH

The SIH was originally formulated based on the observation that primates in general, and great apes in particular, have unusually large brains and uniquely complex social systems. The origins of the social intelligence hypothesis are usually credited to Humphrey (1976). Though Chance

and Mead (1953) and Jolly (1966) had previously developed similar ideas, they were not as widely read or detailed as Humphrey's (1976) work. Chance and Mead (1953) suggested that male-male competition for access to mates in primates may have been a strong driving force in the evolution of the human cortex. Years later, after observing that lemurs have quite complex societies, but do not show the intelligence displayed by simiiforme primates (monkeys and great apes) when dealing with the physical world, Jolly (1966) suggested that social complexity preceded and defined the nature of general intelligence. Independently, Humphrey (1976) suggested that the social realm offers far more opportunity for cognitive challenges than the physical world. He observed that, although primates did not need to be particularly strong innovators, their survival required a high level of practical knowledge about their environment and that this knowledge was acquired socially. This type of society, with mixed age and sex members, creates a degree of complexity where social intelligence can have large payoffs, ultimately leading to the development of culture and human intelligence.

Eventually, with advent of empirical data relating social complexity, social intelligence, and brain size, the SIH became the most popular hypothesis for the evolution of intelligence. Overall, the SIH makes four key predictions: (1) social complexity is the main selective force behind enlarged brains and general intelligence, (2) complex social groups select for greater social intelligence than less complex groups, (3) social intelligence may be transferred for use in the physical domain, and (4) large brains and intelligence are primarily used for solving social problems.

Social Intelligence in Primates

Primates possess many sophisticated socio-cognitive skills (Barrett et al. 2003; de Waal 1982; Seyfarth and Cheney 2012). For example, in complex primate societies, keeping track of relationships among other individuals is critical for access to mates and food resources. Two social cognitive skills of particular interest are recognition of third-party relationships and theory of

mind. Not only do primates recognize other individuals in their group and understand their own relationships to those individuals, but they also recognize the relationships between group members to whom they themselves are unrelated; this entails recognizing third-party relationships. This skill is particularly interesting because, although remembering as many as 100 other individuals in a primate group may be difficult, the number of pair-wise relationships that are possible, even in small groups, is combinatorially massive and thus intellectually challenging (Seyfarth and Cheney 2015). Theory of mind, which is the ability to recognize mental states in other individuals, is an advanced cognitive skill that helps predict the actions of others. Theory of mind likely came about as a result of social pressures in humans, but the rudiments of this ability appear to exist in the great apes (Call and Tomasello 2008). For a more complete summary of primate social intelligence, see Barrett et al. (2003), Cheney and Seyfarth (1985), and Seyfarth and Cheney (2012). Today, a vast number of social cognitive skills have been observed in primates such as reconciliation, reciprocity cooperation, and communication to name a few. In general, the great apes appear to outperform monkeys, which correlates with the greater brain size observed in great apes. The presence of sophisticated social cognition suggests a strong degree of selective pressure for such skills, and these skills are related to fitness in primates (Seyfarth and Cheney 2015). This research supports the idea that selection has favored the evolution of social intelligence.

Social Correlates with Brain Size in Primates

Interest in the SIH grew with the advent of research that correlated specific measures of social complexity with measurements of brain size in primates. Group size was the first quantitative measure of social complexity, and it was correlated with a quantitative measure of brain size (Dunbar 1998). Group size was chosen as the key measure of social complexity because primates interact individually, in potentially fitness-affecting ways, with every member of their groups, and because it is an easy number to obtain for most species. The ratio of the neocortex

to the rest of the brain was preferred in much of the research on the SIH because body size is a much more evolutionary labile trait than brain size. Other measures that were also related to neocortex ratio include tactical deception, grooming clique size, rates of social play, type of mating system, and the presence of long-term stable social bonds (Dunbar 1998; Dunbar and Shultz 2007). Rates of social learning have also been associated with multiple measures of brain size (Reader and Laland 2002).

Defining Social Complexity

Most of the aforementioned studies relating brain size to some aspect of primate sociality also purported to identify the factor that makes primate groups socially complex. Group size remains the most popular measure of social complexity across all species despite its shortcomings, and no other measure has quite been able to replace it, despite varied proposals regarding what makes an animal society complex. Other measures of social complexity that have been studied are fission-fusion dynamics, complex alliances, presence of a linear dominance hierarchy, transactional interactions, or even crèches (for a review and critique, see Bergman and Beehner 2015). de Waal and Tyack (2009, p. 1) suggest that a commonality underlying various research on social complexity is the idea that individual animals must “keep track of interactions with other individuals with whom they must compete and cooperate.” Complex groups are those in which there are many such individuals; simple groups are those in which individual members are largely anonymous.

Primates certainly appear to possess sophisticated social intelligence, but social intelligence itself might be the cause of social complexity, which creates a level of circularity (Gigerenzer 1997). However, others argue that one *must* include social intelligence in the definition of social complexity, because social complexity is hypothesized to be cognitively demanding (Bergman and Beehner 2015). Thus, when researchers attempt to define social complexity, they should attempt to identify the cognitively demanding features of a social group. Using this logic, Bergman and Beehner (2015, p. 204)

suggested that social complexity should be defined as “the number of differentiated relationships that members of a species have with conspecifics.” This definition provides an objective and easy to quantify metric where cognition is clearly required to differentiate group members. Unfortunately, no definition of social complexity has been agreed upon to date; this is a major shortcoming of the SIH because social complexity is *the* key independent variable of the SIH.

Summary: Primates Are Specialized for Social Intelligence

Overall there is good evidence supporting the SIH in primates. Primates possess sophisticated social intelligence, many measures of social complexity correlate with brain size, and primate intelligence appears to be highly social in nature. Specific neurons and multiple brain regions have been found in primates that are specialized to respond to social features of the environment; this supports the idea that social complexity among primates favored “social brains” (Brothers 1990; Frith 2007). In addition to possessing sophisticated social intelligence and complex societies, primates excel at technical skills which require general intelligence (Byrne 1995; Reader et al. 2011). However, the causal relationship between these variables is unclear, and there is a dearth of evidence suggesting that social complexity leads to general intelligence in addition to social intelligence. In sum, primates appear to have social brains, and it also appears that their social complexity does relate to social intelligence, but this social intelligence may be more modularized than the SIH predicts. Research on the SIH is limited outside of primates, and support is much more mixed in non-primate taxa.

Testing the SIH in Non-primates

Mammals

Group size does not explain variation in brain size in carnivores (Finarelli and Flynn 2009), instead the hunting of large vertebrate prey best explains brain size (Swanson et al. 2012), nor does physical problem-solving skill relate to sociality in carnivores (Benson-Amram et al. 2016).

Extensive research on spotted hyenas, which have societies that exhibit convergent evolution with those of cercopithecine primates, provide an interesting case study into the evolution of social intelligence (Holekamp et al. 2007). They exhibit comparable social cognitive skills on every measure tested, including the recognition of third-party relationships, and compared to other hyenids, they have larger brains, are more social, and are better at tasks of physical problem-solving (Holekamp et al. 2015). Taken together, the data from Hyaenidae strongly support the SIH. However, compared to cercopithecine primates, spotted hyenas are small brained and poor physical problem solvers which contradicts many predictions of the SIH when considering their convergent sociality. In bats, living in stable social groups and smaller teste size were associated with an increase in brain size (Barton and Dunbar 1997; Pitnick et al. 2006). Within gregarious ungulates, those that live in stable year-round groups of at least six individuals had the largest brains (Pérez-Barbería and Gordon 2005). Another study found that monogamous ungulates that lived in mixed habitats had the largest relative brain sizes. Elephants are some of the largest brained and longest lived mammals; they are extremely social, forming differentiated relationships with many individuals. Like primates, elephants use tools and may have the rudiments of theory of mind (Hart et al. 2008). In cetaceans, pod size and relative brain size are associated (Marino 2002). Cetaceans also exhibit remarkable convergence with primates of cognitive abilities in both social and physical domains (Marino 2002; Marino et al. 2007). As cetaceans are among the largest brained mammals, this convergence strongly supports the SIH. A large study that included data from both the mammalian fossil record and extant species showed that increases in brain size in mammalian taxa across evolutionary time were associated with greater proportions of species, but not all species, within those taxa living in stable bonded groups (Shultz and Dunbar 2010). This provides some support for the SIH but does not explain the fact that many extant mammalian species with large brains are *not* social (Holekamp and Benson-

Amram 2017). In sum, varied measures of social complexity sometimes correlate with brain size in mammals, but this relationship is not consistent, and there are notable exceptions to this relationship (e.g., bears).

Birds

Birds are capable of many of same feats of social cognition and tool use as primates (Emery and Clayton 2004; Marler 1996). Beauchamp and Fernández-Juricic (2004) found no relationship between either mean or maximum flock size in birds and forebrain size, possibly because flock size is not a stable trait in most bird species. However, Burish et al. (2004) found that telencephalic volume fraction, a measure similar to neocortex ratios in primates, was related to a categorical measure of social complexity. Corvids, in particular among birds, appear to show convergent evolution with apes when it comes to brains and intelligence. Though corvids have smaller overall brain sizes, their relative brain to body size ratio is almost the same as that in chimpanzees (Emery and Clayton 2004).

In a large study that included several mammalian and bird taxa pair-bonding was found to be the strongest predictor of brain size. One explanation for why pair-bonding, as opposed to group size, is related to brain size outside of primates is because any groupings larger than a pair-bond in non-primates could be temporary aggregations or involve undifferentiated relationships (Dunbar and Shultz 2007). That is, primate relationships might be uniquely bonded such that group size approximates the number of bonded relationships only in primates. However, we now know that many species outside of primates do form stable bonds outside of pair-bonds (e.g., spotted hyenas or elephants). In addition, recent research that specifically examined bird species that *do* live in long-term stable groups found that stable groupings larger than the pair-bond were associated with smaller brains (Fedorova et al. 2017) contradicting the idea that long-term stable bonds might be the main cause of social complexity and larger brains.

Fish

Fish have both relatively and absolutely small brains, but fish have been shown to exhibit social intelligence with a diverse array of social cognitive skills documented, including reciprocation, transitive inference, coordination and cooperation, and the ability to remember past interactions with other individuals (Bshary et al. 2014). This research suggests that relatively simple brains can accomplish many of the same feats seen as intelligent in primates, which at the least suggests that a closer look at the rules governing social behavior may be required to measure social intelligence. That is, not all complex social behavior may be indicative of social intelligence. However, in one clade of fish, increased telencephalic size was related to monogamy (Pollen et al. 2007) which, similar to findings in birds, suggests pair-bonds may be related to relative increases in brain size.

Invertebrates

Insects possess remarkably miniaturized brains but can also show highly sophisticated social skills, among other cognitive abilities. This research suggests that brain structure or function may be more important to social intelligence than brain size (Lihoreau et al. 2012). Octopuses also provide an interesting case study. They are large brained relative to other invertebrates and show high general intelligence; they use tools, differentiate individual humans, and show advanced performance on a variety of cognitive tests (Darmaillacq et al. 2014); however they are strictly solitary. Overall, invertebrates possess a rich repertoire of cognitive abilities, which challenges the assumption of the SIH that complex cognition requires a large brain (for a full review of invertebrate cognition, see Roth 2013).

Conclusion

Overall, the SIH explains substantial variation in cognition and brain size within primates, particularly between monkeys and apes. Primates, including humans, do appear to have brains specialized for social cognition, and primate intelligence may be primarily social. Outside of

primates, both support and opposition have been found for the SIH; it is not yet clear what the major selective force favoring large brains and intelligence might be outside of primates, though sociability may have played a role. Certainly, the SIH has drawn attention to the fact that cognition in the social realm is both varied and complex and has a strong impact on fitness and daily lives of animals as well as highlighting the role sociability may have had in human brain evolution. Humans, as well as possessing high general intelligence, are largely unique in the realm of social cognition with regard to our language and culture.

However, the SIH still faces several serious challenges in addition to the described challenges defining social complexity. The SIH has yet to adequately account for grade shifts between different taxa. When comparing brain size to body size, or some other scaling variable, there are marked differences in the y-intercepts or slopes of the regression lines for different taxa. These grade shifts can bias measures of relative brain size and are often not taken into account when comparing measures of brain size to measures of social complexity. For example, orangutans are relatively solitary compared to other apes, but also large brained, in part because the great ape lineage lays on a higher grade than other primates (also see Finarelli and Flynn 2009). A recent paper that reanalyzed the data from primates using updated phylogenies and a larger number of species found no relationship between several measures of social complexity and brain size. Instead, frugivory was the strongest predictor of brain size (DeCasien et al. 2017). Frugivory may require both technical skill through the extractive foraging of fruits and seeds and increased spatial cognitive abilities for remembering when and where to find ripe fruit; this would tend to support ecological hypotheses for brain evolution rather than the SIH (Parker 2015). This finding highlights the fact that the SIH cannot explain general intelligence. Though the SIH hypothesizes that social intelligence may be used to solve physical problems, it seems that social intelligence instead is quite specialized; there is little evidence for transference between social and general intelligence. Though specialized social skills are related

to size of certain brain areas, there is a lack of research that directly relates social intelligence to brain size.

Despite these problems, the SIH currently remains one of the most popular hypotheses for the evolution of intelligence. Overall, there is ample evidence to support the claim that social complexity, large brains, and intelligence are strongly associated in many taxa. Just why or how they are related, and what selective pressures are involved when they are not related, must still be determined.

Social Learning

Wayne Leahy
Macquarie University, Sydney, Australia

Definition

In humans, social learning can take many forms. It can occur within academe, outside academe, as group learning and individual learning. We have evolved as social and learning beings.

Introduction

It may be stated that the role of evolution (Darwin 1859) has not been embraced widely by researchers in psychology and social scientists. However, increasingly, a number of contemporary scholars have suggested that the evolutionary process enables a better understanding of human cognition and socialization (e.g., Geary and Berch 2016; Bjorklund and Ellis 2014; Sweller 2008; Wellman 2014). To discuss the numerous ideologies of evolutionary psychology and their associations with social theories is beyond the limits of

this chapter, therefore, it will concentrate on two major perspectives. These are from Sweller's cognitive load theory and Geary's evolutionary cognition theory. They provide evidence from an evolutionary standpoint of how our memory system and cognitive abilities developed and the implications for learning. These are not the only way to look at the domains but they do provide some compelling evidence.

Cognitive Load Theory

Cognitive load theory (Sweller 2016) is a cognition theory originating in the mid-1970s related to our human memory system structures. Since its foundation, the theory has provided a framework for thousands of empirical studies in educational psychology and instructional design.

The theory is based upon substantial evidence that we acquire and process information via a very small, limited, finite working memory. It has been demonstrated that the recall limit after being shown novel information (e.g., a set of numbers or letters) is seven plus or minus two items (Miller 1956). Later research suggests it is possibly less at four plus or minus one (Cowan 2001). Furthermore, Peterson and Peterson (1959) established that the duration of working memory recall of items is only up to 20 s.

Without a strategy to process the held items, the novel information is lost forever. This is on the proviso that there is no strategy available such as grouping into meaningful blocks or chunks (Miller 1956). As an example, when faced with the task of recalling a random ten digit number (such as a new cell phone number), recall fails after around the first seven to nine digits then may only be retained for the limited time. Fortunately, working memory does interact with, as far as we know, an unlimited capacity long-term memory (Ericsson and Kintsch 1995).

Long-term memory is composed of prior knowledge in the form of hierarchical organized networks of the schema (Miller 1956). De Groot's foundational research with chess masters versus chess novices indicated that master chess players do not have a larger memory system compared to

novice or *weekend* chess players but more schemas in the form of previously remembered chess board configurations (see De Groot 1965 for a full description).

An Update of the Theory Aligned with Evolutionary Psychology

As aforementioned, cognitive load theory is based on the premise that if the characteristics of working memory capacity and duration limitations are ignored when instructional design procedures are developed, an incomplete, or failure of learning will result (Sweller 2016). When the theory was developing, it was based on the interactions between working and long-term memory. These interactions are still completely valid. However, it was not established that there was an association with the theories of evolution. Evolutionary cognition theories mapped against what we now know about contemporary cognitive architecture has been able to afford context and given substantial explanatory power to cognitive load theory and provide a wider range of hypotheses. Sweller is not unique in his analysis of cognition linked with evolution it has been comprehensively elaborated on by others such as Geary (2005), Campbell (1960), and Darwin (1859). Critically for this chapter, a latter reinterpretation of cognitive load theory by Sweller and Sweller (2006) specifically uses five principles aligned with evolution theory. These are the *information store principle*, the *borrowing and reorganizing principle*, the *randomness as genesis principle*, the *narrow limits of change principle*, and the *environmental organizing and linking principle*.

The *information store principle* indicates a very large knowledge base is essential. In nature, the storage facility is genomes which are also immense in holding of genetic information. Although there is no agreed information unit size for a particular genome capacity, it is in the thousands of smaller genomes and much more for larger genomes (Stotz and Griffiths 2004). So too for the store of human long-term memory as it has, as far as we are aware, an unlimited capacity for holding information. Our long-term memory

holds so much that if we were asked to write down all our knowledge, the task would probably be endless. As humans, we can hold simple information from minimal concepts such as an exclamation mark and a comma. We retain that a lemon is yellow and an egg is oval. We also hold larger procedural networks of how to use a pen, drive a vehicle, write a computer program, or read a spreadsheet. All this knowledge plus vastly more is retained in our long-term memory.

The *borrowing and reorganizing principle* for natural information systems is attained during either asexual or sexual reproduction. Prior hereditary lines are the providers of the information. In the case of sexual reproduction, that information is necessarily reorganized as an essential part of the process. Genetic information does not replicate to the identical. For example, offspring are usually similar but not an indistinguishable duplicate of their parents. Likewise in an equivalent process, the majority of the acquired knowledge kept in long-term memory is not a reproduction of the borrowed information and is always changed in some way. Sophisticated communication is an indication of how humans have evolved to acquire most of their information from each other. A learner borrows knowledge by observation, listening, and reading from what others write. Almost all we know is borrowed knowledge. We emulate what others do (Bandura 1986). We imitate other's gestures from infancy. For example, a child comes to understand that "clapping" is used as a signal of appreciation (at least in Western society). In addition, we listen to information from family members and the media. We utilize text to increase our knowledge in a domain. This process involves reorganization, in that new material must be combined with previous material stored in long-term memory using a constructive and reconstructive process.

Unique information is also created from the evolutionary process. Natural selection does so by a random mutation, which is a necessity and the primary source of all biological differences. Similarly, the *randomness as genesis principle* is based on the foundation that, if knowledge cannot be borrowed from others, learners have to randomly create new knowledge and test it for

value during problem solving. When faced with a novel problem all we can do is test it against previous learnt knowledge retained in long-term memory. This in turn generates new knowledge that we deem is either effective or ineffective. Effective new knowledge if, of use, can be retained in long-term memory while ineffective new knowledge is discarded.

To illustrate, if faced with four potential trails while being lost on a walk, we can only choose one and proceed. If it is ineffective we will turn back and choose one of the three remaining trails. The strategy will continue on until we discover the correct trail. The productive trail is retained in long-term memory and the others discarded. Clearly a random generate and testing procedure could result in an unworkable number of possible outcomes if there were too many trails. As another example, consider that there are two elements of A and B that need to be combined but there is no prior knowledge available of the correct combination. Using a random generate and test procedure, the permutations for A and B are 2. A combination of A, B, C, and D is more difficult to determine as the permutations are 24. For 7 letters, the total is 5040 permutations. If we must deal with 10 elements, there are 3,628,800 permutations. This has the task of problem-solving essentially unmanageable. Due to the number of possibilities, the combination of just 10 items, or even 7, will take much longer and clearly be beyond the limited capacity and duration of working memory.

Evolution by natural selection as well imposes restrictions on the possible generating number of mutations. A genome is generally limited in the number of changes to its genetic composition. Variations are usually slow and incremental as too many alterations could be unproductive or fatal. Genetic mutations thus are slight and occur over a prolonged and measured period. Similarly, the *narrow limits of change principle* is a safeguard that variations to long-term memory are minor and incremental due to the very limited capacity and duration of working memory. The quantity of randomly created new knowledge has to be restricted to preserve the functionality of the information stored in long-term memory.

The *environmental organizing and linking principle* endorses the previous four principles outlined. In nature, this final principle assures that a change is suitable for the prevailing environment. The environment does influence fluctuations to the information store however, the eventual goal of this store is to permit adaptive functioning in the given environment. The epigenetic system here is the stable governor and can turn genes on and off after cell division. Regardless, it does so evenly. The environmental organizing and linking principle similarly show that working memory is restricted when processing novel information, it has however much extensive, unidentified boundaries when processing known information imported from long-term memory.

The Link Between Cognitive Load Theory and Geary's Evolutionary Cognition Theory

The updating of cognitive load theory and implications for instructional design is due to the relationship with Geary's theory. Many aspects of Geary's thesis have been implemented and supported by contemporary cognitive load theory research. In addition, previous theoretical problems with cognitive theory insofar as findings have been clarified. Geary (2006) and Geary and Berch (2016) suggest evolved and nonevolved abilities have equivalency between natural selection and human learning to provide instructional procedures. Some knowledge is inherent and will need no instruction. Geary divides knowledge into what is known as *biological primary knowledge* and *biological secondary knowledge*. The two categories align with Sweller's theory in that it is only biological secondary knowledge that requires an awareness of the constructs of our memory system and implications for instructional design. This will be explained in the following section.

Biological Primary Knowledge

Biological primary knowledge tends to be concerned with generic skills that are essential to

human functioning. It is knowledge that we need to function at least basically in a society. It can be termed a *cultural knowledge*. Clearly, there are numerous adaptive difficulties accompanying a navigating of the social world. Humans have to maintain allies, manage status hierarchies, cope with the competing interests of others, interact with groups and other group members, coordinate social activities, and participate in joint decision-making. Humans have to create favorable conditions using others to their benefit and avoid being used by others for gain.

As well, they have to deal with the realities of the physical world. This is exactly what happens in the natural world (Geary and Berch 2016). A species has to cope with the competing interests of other species, create their own habitats, share their own habitats, and avoid certain habitats of other species. Species need to utilize other species by hunting and evade being used by others by avoiding becoming quarry.

We too as humans have evolved to acquire this knowledge automatically. To reiterate, it is that knowledge we really do not need to be explicitly taught. The capacity to learn our first language is a necessity for our species, and it is required of us to communicate verbally. The commencement of speech is an example (Kuhl 2000). The ability of toddlers with virtually no training to learn and be motivated to learn their first language (to the extent of at least being understandable) by listening is biological primary knowledge. An infant does not need instruction to utter sounds as it will make its first sounds independently. To teach a child to make a word needs to consider the physical mechanics needed to make the sound of the word. It requires a concurrent arrangement of lips, tongue, breath, and voice (Sweller 2008). Yet, without any explicit instruction, a child can independently verbalize this word and others at some stage of its development.

To be mobile is crucial and a child does not need to be taught how to rise upon its legs and take its first steps. Similarly, the recognition of faces (Bentin et al. 1999) is essential and a child has no need to be explicitly taught to distinguish parents, caregivers, family, or friends. As well, a child is able to read emotions from facial expressions and

can follow the gazes and gestures of others (Herrmann et al. 2007). In agreement is Bandura (1986), who states that the knowledge to imitate is a skill that has no need to be taught. Imitation is exhibited at an early age where young children will commence to frequently imitate the *other* without instruction. Although Piaget demonstrated this to occur at a later age of around two onwards (Piaget 1951), it is shown to commence as early as 6 weeks where babies imitated facial expressions of the mother (Meltzoff and Keith Moore 1994).

Biological Secondary Knowledge

The second category of biological secondary knowledge is information where instruction is certainly required. This class of knowledge is different from the first of biological primary knowledge as it is culturally specific (Sweller in Geary and Berch 2016). To be literate and numerate are skills that are needed to be explicitly taught. Educational institutions teach biological secondary knowledge to the members of its society to enable full and successful participation in that society. For example, academe usually instructs in language, mathematics, science, history, geography, and economics among other subjects in a curriculum. The knowledge within these domains are not automatically inherent in the genesis and progression of the human mind and therefore needs instruction.

Pronumerals and algebra as well are examples of biological secondary knowledge. That the pronumeral a can have a value for one equation and another value for an alternative equation must be specifically taught as well as the procedures to solve equations. We are not genetically programmed to spontaneously comprehend these type of mathematical constructs. In English, to comprehend that within our grammatical rules, a sentence must have a subject, is not a tacit construct for us. As infants, we may be able to learn to speak our first language by simply listening as it is biological primary knowledge. However to speak our language fluently, as required by our society, requires the biological secondary knowledge of the rules of grammar. An infant's biological

primary knowledge attained expression of *Me want drink* is not a grammatical sentence.

David Geary's categorization of knowledge is a logical proposition. The connection between the second category of biological secondary knowledge then has implications for learning and the role of explicit instruction.

Discovery Learning Versus Explicit Instruction?

For at least a half a century, there has been an energetic belief in many educational circles that we learn more efficiently by a *discovery* approach. Exemplified by Jerome Bruner in Bruner 1961 and Seymour Papert (1980), the philosophy has had many variants where labels such as *discovery learning*, *problem-based learning*, *inquiry learning*, *constructivist learning*, and *experiential learning* are exemplified (see Kirschner et al. 2006). The Piagetian theory of the construction of knowledge is also related here. The terminology tends to signify the same constructivist/discovery view point of emphasizing *minimally guided instruction* for the learner. It seems that a driver for the movement is an argument that travels along the following lines:

An immense amount of information and knowledge is learnt *outside* educational institutions. Furthermore, this information and knowledge are accumulated with ease and without intervention of an instructor. If this information is absorbed without structured, explicit methods and is successful, then it must be a useful paradigm. Moreover, the artificial methods by which we teach such as guided or direct instruction and transmission from a teacher must be insufficient. Certainly, the argument goes, current teaching methods are not exemplified by students learning syllabus content with ease and without intervention. So, we must then utilize the way information is absorbed in the *outside* world for use *inside* the educational institutions. If people learn by being *immersed* in a society/culture we can then immerse students in a subject or topic and thus somehow they will accrue the required knowledge and more importantly obtain *understanding*.

A common example of the unguided method is in science instruction. Students are placed in inquiry learning contexts and have to discover recognized principles by demonstrating the investigatory attributes of professional researchers (Van Joolingen et al. 2005). Another illustration is where university medical students in problem-based learning (PBL) courses are urged to find solutions for patients' common conditions using problem-solving techniques (Schmidt 2000). Guided, direct instruction and rote learning were deemed to be unproductive. Yet, what has been outlined in this chapter regarding secondary biological information and its processing by our cognitive architecture makes clear that having one discover information alone is not efficient. There are too many possibilities for a discovery path which may overload working memory.

There is no compelling empirical evidence that discovery approaches are efficient methods of learning in spite of decades of research. In stark contrast, there is a large body of evidence from numerous controlled empirical experiments that the epitome of direct instruction, that is worked examples, are substantially superior as instruction (see Renkl 2005). A worked example is a step by step guide given to novices in a domain that shows the solution to a problem. The alternative would have a learner discover the answer.

Consider the following algebra problem: $a + b = d$ solve for b where $a = 3$ and $b = 4$. A full worked example would give a step by step guide in perhaps less than 8 steps. However, a novice with minimal prior knowledge in the domain may not find a solution at all, or at least take some time to *discover* a correct solution. The reason for this is our human cognitive architecture. Working memory may be faced with numerous possible solution paths and be overloaded resulting in a learning failure.

Research on the traditional use of worked examples has shown that usually one or two worked examples are given then they are followed by a number of similar problems to solve. This is ineffective, and instead, it is more productive to have many worked examples initially, then followed, by similar problems to solve (Sweller and Cooper 1985).

As another example of the debate, *rote learning* is a strategy that within a discovery learning philosophy is frowned upon. Discovery type learning appears to use the rationale that better *understanding* within the learner is developed and certainly no understanding will ever develop by *rote learning*. A problem with this premise is that *understanding* is not defined (Sweller 2008). We know that the way our human memory system operates is critical for learning so it would be now used to look at what we mean by *understanding* as well as *rote learning* and how they could be placed within the operation of this system.

Although this may not be evident under a discovery learning philosophy, both understanding and rote learning are crucially dependent on our long-term memory store (Sweller 2008). Elementary math learning of tables by novices is an illustration of rote learning in early education. If a child can rote learn that $5 \times 9 = 45$; that knowledge is then stored in long-term memory. If the child can also understand that $\times$ means repeated addition so that $9 + 9 + 9 + 9 + 9 = 45$; this too can be stored in long-term memory. It is not the case that the first is stored and the second is not. What is more important is the differences between the two in the structure of the learning content. Learning with understanding requires large amounts of connected information stored in long-term memory. To make those connections imposes a huge amount of cognitive load on working memory during initial processing to have them stored in long-term memory. Thus as an alternative strategy, novice learners will rote learn (Sweller 2008). Learning with *understanding* does not negate the function of long-term or working memory. It means that learning with understanding results in a large amount of linked information needed to be stored in long-term memory. This linked information has features that are difficult to process in working memory. If we return back to the algebra worked example illustration previously as researched by Sweller and Cooper (1985), the continued processing of a number of worked examples initially results in more linked knowledge. This is then stored in long-term memory and therefore resulting in better *understanding* of, in this case, basic algebra.

Schooling, Observation, and Learning

An integral feature of social learning theory is people's observation of another (the model). The observation takes part within the context of social interactions and experiences. A model carrying out a behavior and the significance of that behavior is recalled with the order of events. The information is then utilized to guide following behaviors (Bandura 1986). Humans do not learn new behaviors merely by testing them and having a resultant achievement or failure. Observing a model can also prompt the viewer to engage in behavior they already learned. To be able to reproduce the actions of others including reproducing the *learning* of others could be viewed as the survival of a species. Educational institutions such as schools, colleges, and universities were set up for this reason. Too, they are not only considered as sites for social learning but also "content" learning. As previously outlined, almost all we know has been directly perceived or learnt through another person or group. Geary's category of biologically secondary knowledge covers the types of information that is found in every syllabus area within an educational institution. School was devised for the teaching of biologically secondary knowledge. This category of knowledge is unlike primary knowledge and is not likely to be attained without the constructs and tasks established in educational institutions (Sweller 2015).

Domain General and Domain-Specific Knowledge

According to Sweller (2015), knowledge that is *domain general* can be considered as *generic* and is aligned with Geary's biological primary knowledge. As outlined previously, they are essential human functioning skills that we have genetically attained without instruction. When solving any problem, the looking at differences between the goal and initial state of the problem and minimizing these differences is a first general problem-solving heuristic (Newell and Simon 1972). For example, when faced with a novel problem in

direction, we automatically look for differences in the present state of where we are, compared to the goal state of where we wish to go. We just do not inertly stand there. The knowledge is generic, essential for the survival of our species and does not have to be taught. A secondary response of studying the position of the sun or stars if possible as direction indicators is an example of *domain-specific knowledge* and has to be attained by prior instruction. Other examples of domain-specific knowledge are mathematical operations, the grammar of a language, chemistry principles, and computer coding or medical procedures. These too require detailed training. Educational institutions were established to address the need to teach domain-specific knowledge (which really can be considered biologically secondary knowledge). The chapter will now outline a cognitive load effect related to socialization.

A Collective Memory Through Socialization

Pass and Sweller (2012) state that from the viewpoint of evolution, natural selection supports the “fittest.” According to Brem et al. (2003), self-interest would appear to be a dominating and predisposing force for an individual. Furthermore, Richard Dawkins even labeled this tendency the “selfish gene” (Dawkins 1989). Although this argument of selfishness is questioned due to definitions (see Hawley 2016 for a fuller account), co-operation has the potential of strengthening the group with joint available resources rather than an individual working independently.

The use of group work in educational institutions is common. Group work can be defined as a small group of students who collaborate to learn and complete tasks. Humans working as a group in many situations can provide an individual with information more expediently, than trying to obtain that information without support from a group. In a group, detailed individual knowledge is not a requirement. Clearly, the group can access more resources than when working individually. A team of collaborating learners may

well be able to solve complex problems that may be insolvable for an individual learner (Pass and Sweller 2012).

Paas and Sweller have completed research related to this termed the “collaborative learning effect.” Recall, the borrowing and reorganizing principle (Sweller and Sweller 2006) where borrowing and reorganizing information from others is the main source of our knowledge. Correlated with this principle, is that rather than acquiring information alone, information can be better learned by us from an instructor or via instructional materials.

The collaborative learning effect is where during shared learning, that information can be obtained from other sufficiently knowledgeable people engaged in the same task (Pass and Sweller 2012). The effect has been demonstrated in cognitive load research comparing an individual to collaborative learning environments. The Pass and Sweller contribution is more empirically specific than that of Vygotsky and his construct of the *Zone of Proximal Development* (Vygotsky 1962), where terminology and specific outcomes have been accused by some critics as vague.

A detailed examination of group work from a cognitive load perspective will be now outlined: A co-joined working memory has the potential to increase the ability of the group producing a larger working memory. The elements of information necessary for a learning task can be divided between group members so memory load is shared by the group cognitive capacity. Note that *general* communication and coordination between the group members is a requirement as well; however, this is a biological primary knowledge process that has evolved and is not needed to be learned. Whereas the content of the learning task is biological secondary knowledge. Yet the collaboration (group work) versus independent (working alone) approach has two contrary consequences (Paas and Sweller 2012).

Firstly, a substantial working memory load can be inflicted by the learning material (the biologically secondary information). However, that can be shared over several cooperating members so that they have to devote less cognitive effort than

if they were learning alone. As a result, a large reduction in a singular working memory load can be distributed among group members. Secondly, by dividing the work the communication and coordination processes (group interactions) require the group members to invest an additional cognitive effort, which is an effort that individuals do not have to exert.

This cost of group interactions can be further divided into two categories of biologically primary knowledge or biologically secondary knowledge. The working memory costs of general group interactions may be minor because they are biologically primary. In contrast, the working memory costs of the task-specific group interactions may be considered because they are biologically secondary information. Consequently, a prospective advantage of group learning may only be evident if the working memory costs are largely biologically primary. According to Serfaty et al. (1998), the working memory costs of task-specific communication and coordination processes can be reduced by teaching those processes or by working in carefully designed learning settings.

Conclusion

From this chapter, evidence has been presented that our memory system has proceeded through evolution and developed to make us what we are. As outlined in the Introduction, these perspectives from David Geary, John Sweller, and others are not the only way to look at the domains but undoubtedly compelling ones. The interactions between evolution and our human cognitive architecture may enable a better understanding of why, what, and how we learn in both a social and educational context.

Definition

Social learning as posited by Bandura (1977) states that all individuals learn from each other by means of observation, modeling, and imitation. Cognitive learning theory states that mental processes (i.e., learning) are influenced by both intrinsic and extrinsic factors. Social cognitive theory states that learning is directly associated with observing others and engaging in social interactions.

Introduction

The three basic types of learning theories include behaviorism (e.g., Skinner), social constructivism (e.g., Vygotsky), and cognitive constructivism

(e.g., Piaget). Within social constructivism one finds social learning theory, and within cognitive constructivism one finds cognitive learning theory.

Social learning theory as posited by Bandura (1977) states that all individuals learn from each other by means of observation, modeling, and imitation. Bandura's model includes attention, memory, and motivation as factors in learning. It has been said that social learning theory is a bridge between behaviorism and cognitive learning theories. Bandura believed in "reciprocal determinism" or when individuals jointly learn from each other.

Cognitive learning theory has grown out of cognitivism (Piaget) where learning occurs internally in response to experiences. Cognitive learning theory states that mental processes (i.e., learning) are influenced by both intrinsic and extrinsic factors. What occurs within the learner is as important as to what occurs in the environment. Cognitive learning theory encompasses social cognitive theory and social behavioral theory (Bandura 1977). Social cognitive theory states that learning is directly associated with observing others and engaging in social interactions.

Social learning and social cognition encompass many overlapping layers of cognition, social learning, language, and culture. Because these layers are overlapping, it is impossible to determine causal factors among them. However, it should be noted that language is central to all of these layers. Consequently, discussion will focus on the following: (a) language and social cognition, (b) language and social learning, and (c) language and culture.

Language and Social Cognition

Language and social cognition are inseparable. Mathew and Raja (2015) stated that, "Any account of human social cognition cannot get away from language" (p. 6). Social cognition (SC) is the way that one perceives, interprets, analyzes, and uses information about the social world in which we live. Mathew and Raja also stated that, "SC and language together, probably formed an evolutionary cycle where in advances in one could feed advances in the other, and it is unclear what human cognition would be like

without the powerful cultural augmentation that language provides" (p. 7). Social cognition will hereinafter be referred to as simply cognition.

Opposing views of the roles of cognition, language, and culture have emerged over the last 100 years. Fundamental to this review are brief discussions of the philosophical viewpoints of Cognitive Development Theory (e.g., Piaget), Social Interactionist Theory (e.g., Vygotsky), Universal Grammar or Universalist view (e.g., Chomsky), Nativist view (e.g., Pinker), Linguistic Relativity (e.g., Whorf), and Cultural Psychology (e.g., Markus, Shweder, or Rogoff).

Piaget's Cognitive Development Theory (also known as cognitivism) sequences learning according to different developmental stages (sensory motor, preoperational, childhood, concrete operational, and formal operational) (Piaget 1926). Children take an active role in learning and are not just passive learners. Initially children learn through manipulating their environment and sensory exploration (sensory motor phase). During the preoperational phase, children begin to think with words and symbols. In the concrete operational phase, children begin to think logically and their thoughts become more organized. It is not until the Formal Operations stage that children begin to think abstractly. Hence, Piaget's approach focuses on early learning and sequential development of cognitive processes. Other cognitivists include Vygotsky and Bruner.

On the "other end" of the philosophy continuum, one finds Social Interactionist Theory that incorporates aspects of developmental theory (Piaget 1926) and information processing model (MacWhinney 2005). Vygotsky was an early proponent (1962) of the idea that social interaction with others, particularly more experienced language users, plays an important role in language learning. Vygotsky suggested that social interaction is key to learning and consequently he proposed the zone of proximal development (ZPD). ZPD is the difference between what a learner can do and she/he cannot. The zone of proximal development is the area where a learner needs assistance from someone with higher skills. This is accomplished through scaffolding. Scaffolding is the process of encouraging learners through

progressive stepwise levels. Scaffolding was coined by Jerome Bruner and attributed to Vygotskian learning. The ZPD and scaffolding encompass Vygotsky's social and cognitive learning.

Noam Chomsky is best known for his belief in universal grammar and consequently the Universalist view of cognition (Chomsky 2006), i.e., language principles are innate and fixed (nativist view). According to Chomsky, the ability to learn grammar and language is hard wired into everyone's brain. In addition, language ability develops without being taught and in the absence of external stimuli (i.e., poverty of stimulus). The Universalist view grew out of universal grammar and espouses the belief that all human beings share a common set of cognitive abilities and that cultural variabilities and influences are nonexistent or negligible (Pinker 2002).

The separation of cognition and language and how language is acquired is still debated. However, most researchers will agree that cognition and language are inseparable and intertwined (i.e., whether a weak or strong connection exists). The role of language and culture has also been extensively disputed. The theory of Linguistic Relativity is discussed next.

The theory of Linguistic Relativity suggests that language affects how individuals see and construct their world (Lucy 1997). Lucy defines linguistic relativity as, "The linguistic relativity hypothesis, the proposal that the particular language we speak influences the way we think about reality, forms one part of the broader question of how language influences thought" (p. 291). Linguistic Relativity evolved from the earlier works of Benjamin Whorf (1956). Whorf believed that difference in language grammars and how the languages are used affects the manner and way in which speakers perceive the world and their environment. One can postulate that language is constructed and learned and therefore, a reflection of culture (Lucy 1997).

Cultural Psychology as defined by Shweder (1991) is the manner in which culture expresses and changes the mind resulting in cultural and ethnic diversity. This approach presumes that culture and cognition are inseparable and consequently, cognitive theories in one culture will

have less relevance in another culture. Markus (2013) stated that

Cultural psychology builds on one of the most fundamental ideas in psychology: The products of the mind are a function of the social communities that people are part of. Cultural psychology is an effort to recognize human nature and the different ways of being human (lines 8–9).

Rogoff (2003) states that all children approach developmental learning stages according to the cultural practices in which they have participated. Cultural practices are transmitted through language and social learning.

Language and Social Learning

Acquiring information from interacting and observing others is social learning (Crivello et al. 2018). Most learning takes place in social contexts (Vygotsky 1962). Consequently, social learning leads to enhanced cognitive, attentional bases, social reciprocity, and social communication. Language is the medium by which social learning occurs. Language for social learning and social interaction is pragmatics.

Pragmatics consists of the ability to use language socially and appropriately in given situations (Hymes 1972). Pragmatics is also concerned with how language is used and interpreted. It is thus the study of speaker-listener interactions.

Pragmatics consists of intentions on the part of the speaker to communicate a message. Speakers must have a reason to communicate (i.e., intent). This purpose to communicate occurs early in infancy in the form of nonverbal communications (e.g., smiles, coos) and develops into more meaningful exchanges with the onset of gestures combined with symbolic words. The purpose of a message is illocutionary intent. The actual message (nonverbal and verbal) is referred to locutionary language and the effect it has on the listener is the perlocutionary effect. All speakers must possess presuppositional knowledge of the listener (i.e., what background knowledge must the listener have so that the message is understood?). Children are unable to acquire presuppositional knowledge until they are able to take the perspectives of others (i.e., neo-egocentrism) and the ability to consider several aspects simultaneously (i.e., decentration).

Pragmatics is context specific, i.e., environmental context influences language interactions. And language is also capable of influencing the contextual environment (Hymes 1972). Bates (1976) stated that pragmatics occupies the interface among linguistic, cognitive, and social development. In sum, pragmatics parallels both social learning and cultural learning (i.e., acculturation).

Social Interaction is Cultural Interaction

Social interaction and cultural interaction are governed by rules of communication, which in turn are governed by language. In order to understand social interaction and cultural interaction, one must understand how culture and language (i.e., the symbolic representation of culture that holds meaning to a given group of individuals) are mediated through social interaction (Gibbons 2012). Culture and language define and determine how social interactions impact how individuals interpret their world (i.e., social interaction behaviors and value systems) and how individuals communicate.

Language can designate, associate, denote, or connote meaning (Brice and Brice 2009) and is expressed verbally via oral and written narratives as well as nonverbally through gestures, eye contact, and body language. Cultural variations exist in how language is expressed and used within different contexts. For example, verbal expression of emotions in Western culture may be considered appropriate, while in Eastern cultures this can be viewed as immature and disruptive to social harmony (Fernández et al. 2000). In the nonverbal language domain, some argue that facial expression of emotions is not culturally universal and may contain distinctive nonverbal “accents” and “dialects.” Tuning into these fine distinctions is important in understanding and interacting with culturally and linguistically diverse (CLD) individuals. Therefore, social interaction is complex and dictated by cultural variation, beliefs, and values.

Language and Culture

Defining culture is a complicated endeavor given its variation across domains and purpose, which is embodied within a historical context. An anthropological definition of culture is “that complex

whole which includes knowledge, belief, art, law, morals, custom, and any other capabilities and habits acquired by man as a member of society” (Tylor 1871, p. 1). Culture is also defined by Roseberry-McKibbin (2007) as, “Simply, culture is a dynamic set of values and belief systems that shape the behavior of individuals from various groups and communities” (p. 104).

Culture can be defined according to various continuums of behavior, individualistic vs. collectivistic cultures, loose cultures vs. tight cultures, low context vs. high context communication styles, and horizontal vs. vertical cultures (Triandis 2001). These continuums are not absolute; for example, individuals from collectivistic cultures can display behaviors that are individualistic. It is best to think of these continuums as ranges of behavior.

Individualistic Versus Collectivistic Cultures

Ting-Toomey and Chung (2012) refer to individualism as the broad value of tendencies of a culture to emphasize the importance of individual over group identity, individual over group rights, and individual needs over group needs. In contrast collectivism refers to the broad value of tendencies of a culture to emphasize the importance of the “we” identity over the “I” identity, group obligations over individual rights, and in-group-oriented needs over individual wants and desires.

Hence, individualistic cultures define the self as independent or apart from the group. The focus is on the person and less on the group (Ting-Toomey and Chung 2012). Individualistic cultures rely on internal and personal attributes to explain behaviors, e.g., Diego seeks the teacher’s approval because he needs reassurance. Individualistic cultures also emphasize the “autonomous self” (Ting-Toomey and Chung 2012), the outer portrayal of oneself (i.e., face) is self-oriented and self-driven (Triandis 2001). Individualistic cultures stress direct communication. An example of direct communication is when strangers establish relationships and communicate more openly and freely.

In contrast, collectivistic cultures value indirect communication, social interactions, and non-confrontations. Individuals from a collectivistic culture define themselves as part of a group and belonging to the group (Gudykunst 2003; Triandis

2001). Group participation and cohesion are of paramount importance (Brice and Campbell 1999). Behaviors are explained by collectivistic norms or standards of expected behavior, e.g. Diego seeks teacher approval because the close relationship to the teacher indicates his participation in the group. Collectivistic cultures emphasize “face” or being other-group oriented (Gudykunst 2003). Membership in the group gives one the right to become involved in the affairs of others, e.g., teachers or school psychologists may intercede on a student’s behalf. Examples of collectivistic cultures include many Latino cultures, Asian cultures, Middle Eastern cultures, African cultures.

Loose Versus Tight Cultures

Tight cultures have strong societal norms and low tolerances for deviant behavior (Gelfand et al. 2011). Collectivistic and tight cultures demonstrate a strong distinction between ingroup and outgroup members. Gelfand et al. (2011) also distinguish loose cultures as having weak norms and a high tolerance for deviant behaviors. Membership in collectivistic loose cultures tends to be less restrictive.

Loose cultures and individualistic cultures are a part of the same continuum, whereas tight cultures are associated with collectivistic cultures (Brice and Campbell 1999). Looseness carries the connotation of creativity. This is evidenced in language via word puns and humor. However, not all cultures will exhibit all behaviors consistent with either end of the individualistic/collectivistic or tight/loose distinctions. For example, Cuban culture exhibits traits of creative language use and puns although Cuban culture tends to exist along the collectivistic tight end of the continuum (Brice 2002).

According to Gelfand et al. (2011), the USA is considered to be a loose culture, while Japan is considered to be a tight culture. In comparing Japanese and US American ingroup vs. outgroup standings, Whitting (1989) uses American vs. Japanese baseball as a means of cultural contrasts. The point of ingroup vs. outgroup membership is illustrated when he quotes an American baseball manager in Japan, “All the managers manage differently here. I mean they manage Japanese

style. And I do it more or less U.S. Style. So I’m the one that’s different really” (p. 143). Whitting also exemplifies this point by stating that, “Many Japanese will argue that a foreigner should never be allowed to manage a Japanese baseball team” (p. 143).

Low Context Versus High Context Communication

Hall (1983) initially introduced the concepts of low-context and high-context communication. Low-context communication relies less on the contextual environment for understanding the intent of the message; instead, the majority of the message is found in mostly just the words (e.g., print or formal communication such as speeches). Interaction between the speaker and listener is typically reduced. Low-context communication reflects a logical and linear approach. The direct verbal interactions, overt communicative intentions, and sender-oriented values seen in low context communication are typically found in individualistic cultures (Ting-Toomey and Chung 2012). Low-context cultures tend to attribute one’s behavior to the individual’s personality.

High-context communication attributes behavior according to the situation or factors that are external to the person, i.e., an external locus of control or where one places responsibility for actions (i.e., within oneself or outside of oneself) (Brice and Campbell 1999). High-context communication can be depicted as a spiral communication approach that uses indirect styles of speech, and includes many indirectly related conversations. Verbal negotiations and use of subtle nonverbal nuances are key points. Whereas in low-context communication messages are direct and “to the point.” High context communication is seen in many Hispanic cultures. Brice (2002) in examining communication styles of Cuban-Americans stated that Cuban-Americans exhibit a more indirect communication style, i.e., more spiral as opposed to more linear. Discussion of family, friends, employment, etc., almost always precedes formal topic discussions.

Horizontal Versus Vertical Cultures

Another feature of cultures is the horizontal vs. vertical distinction. A collectivistic or

individualistic culture may be either more horizontal or vertical on this continuum. The horizontal orientation emphasizes that individuals are similar, equal, or parallel on most aspects especially those involving rank or status. In contrast, vertical orientations emphasize rank, privileges of rank, and inequalities associated with rank. (Triandis 2001). Hence, four possibilities exist when combining the collectivistic vs. individualistic and horizontal vs. vertical distinctions: (a) collectivistic horizontal (group/same), (b) collectivistic vertical (group/rank), (c) individualistic horizontal (individual/same), and (d) individualistic vertical (individual/rank).

Individuals from a collectivistic horizontal (group/same) culture accentuate group values, social cohesion, cooperation, and equality among members. Israeli kibbutzim members both are group oriented and membership equality. Triandis (2001) stated that individuals from a collectivistic horizontal background do not want to stand out nor dominate others in a group, and that community needs are valued more than individual needs.

Collectivistic vertical cultures (group/rank) are exemplified by traits of belonging to the group, yet maintaining rank and class distinctions. In Japanese language and culture, the word and concept of “*giri*” signifies honor, duty, obligation, and burden all into one. One is bound to the group and also bound to superiors in fulfilling one’s duty (e.g., to the family and to one’s parents/grandparents) over one’s individual wishes and desires. A hierarchical model is also evident in language and how it is used (e.g., honorifics or the etiquette found in how one addresses another individual based on rank, status, and/or hierarchy). For example, in the Japanese language and culture, one may use the affix “*san*” added to another person’s name that is in the same social station as oneself. “*Sama*” is generally reserved for more elder family members (e.g., *otosama* – father; *okasama* – mother). “*Chan*” may be used as a form of endearment, primarily for children. “*Sempai*” (mentor) is used in workplaces for those with seniority. However, “*kouhai*” is the opposite of “*sempai*” denoting someone of a lower social rank. It is considered rude to employ such a term in speaking with that individual.

Individualistic horizontal cultures (individual/same) place an emphasis on uniqueness and sameness. Sweden and Finland are examples. Communication is respectful but more informal as all individuals are seen as the same. Initiating conversations and maintaining conversations is not burdensome. What may be seen as intrusive in a rank oriented culture is seen as typical in a horizontal culture. Parents and grandparents do not live with their offspring children. Living independently is a valued trait. Individual horizontal cultures are often seen in democratic socialistic governments (especially, the Scandinavian countries).

Individualistic vertical cultures (individual/rank) are focused on self-achievements and obtaining status. Persons from such a culture (e.g., middle and upper SES individuals from the USA) behave in ways to “stick out” or be recognized on one’s individual merits that place one at a higher social status. Taking “selfies” and/or posting on Facebook illustrate the importance of “I” and how to stand out from others. Rank is seen in the form of titles (e.g., Instructor, Lecturer, Assistant Professor, Associate Professor, Professor). The CEO of a company or Dean of a College have the expected honor of having more “talk-time” in a meeting than the employees. Those in superior positions may be allowed to be more direct or blunt in communication.

It can be argued that language and culture are, in essence, inseparable. Dumitrescu (2012) stated that

The inextricable relationship between language and culture has been confirmed by linguistic anthropologists, who have come to the conclusion that language learning is coextensive with culture learning . . . language learning cannot be distinguished from the process of enculturation to which every member of a society is exposed from early childhood (p. 161).

Language is highly intertwined with culture, as it is both a by-product and a constructing mechanism of culture making it difficult to separate the two. In addition, culture also impacts language and how we interact. For example, the word “meal” can be differentiated into breakfast, lunch, and dinner in western cultures. However, there may be no differentiations in other cultures. This distinction of dividing meals into three

different times may not be reflected in agricultural or nomadic cultures. Culture impacts perception, which then influences language, and language which then influences interaction.

In essence, culture shapes how people live, interact, and interpret the world around them as well as what people value. For example, one culture may value independence and autonomy, while another values dependence and cooperation. Culture or shared patterns of behavior, thoughts, feelings, attitudes, and values may differ according to membership of racial, ethnic, religious, or social groups. Furthermore, culture can also differentiate between gender, class, physical and mental abilities, religious and spiritual beliefs, sexual orientation, and/or age.

Conclusion

The three main schools of learning include behaviorism (e.g., Skinner), social constructivism (e.g., Vygotsky), and cognitive constructivism (e.g., Piaget). As a result, the latter two theories have evolved into social learning theory from social constructivism and cognitive learning theory from cognitive constructivism. The key elements of these theories have endorsed social interaction and learning occurring internally in response to experiences. At the key to all learning is the ability to use language in interaction with others and to use language to acquire knowledge.

Hence, language underlies all aspects of social cognition, social learning, and culture. After a certain developmental period when language becomes a child's main means of communication (e.g., in typically developing children, this will occur between three and 4 years of age), then language and cognition become inseparable (Brown and Lenneberg 1954). Learning is mediated through language and social interaction. Social interaction is evident in the child's early life. The Whorf (1956) hypothesis states that language orients learners to specific ways of seeing the world. Duquette (1991) stated that "there is more in the home culture that reflects to language development than might at first appear. In fact,

culture may be to language what language is to speech because they involve each other" (p. 131). Language and culture also appear to be highly intertwined. In sum, language is the key to all learning.

Definition

The evolutionary perspective argues evolutionary mismatch, well-being, social belonging, social monitoring that social media exploits people's evolved psychological mechanisms for social belonging and monitoring, thus explaining why people continue to use social media widely despite its potential harmful effects.

Introduction

Social media broadly refers to platforms that allow for the production and sharing of content online, which include collaborative projects (e.g.,

Wikipedia), weblogs (e.g., YouTube), and social networking sites (e.g., Facebook, Instagram). On the one hand, social media can facilitate the expansion and maintenance of social networks, thereby bringing about improved psychological well-being and life satisfaction (Kim and Lee 2011; Valenzuela et al. 2009) as well as reduced stress via perceived social support (Nabi et al. 2013). On the other hand, a host of nontrivial adverse effects also accompany its usage, such as negative mood (Sagioglou and Greitemeyer 2014), low self-esteem (Neira and Barber 2014), and depression (Morrison and Gore 2010).

As the virtual engagement with others on social media increasingly becomes an integral part of everyday life and carries real-life consequences for its users, the effects of social media and the factors that drive its usage have become key public concerns and received notable research attention (e.g., Kim et al. 2009; Morrison and Gore 2010; Nabi et al. 2013; Neira and Barber 2014; Valenzuela et al. 2009). The current entry reviews some contemporary explanations of social media usage, highlights their explanatory shortcomings, and demonstrates how an evolutionary perspective can address these gaps.

Current Theories of Social Media Usage and Effects

Several theories have been proposed to explain people's extensive use of social media. The cognitive-behavioral model of pathological Internet use (Davis 2001) suggests that positive reinforcements, such as receiving likes, positive comments, and other sources of social validation, entice people to continue using social media. When coupled with underlying psychopathology (e.g., social anxiety, low self-esteem, depression), problematic outcomes occur, including excessive social media use and maladaptive cognitions. Maladaptive cognitions refer to distorted thoughts involving self-doubt and negative self-appraisal, such as "I am only good online" or "nobody loves me offline." Empirical support for this model is evinced from the documented associations between depression and pathological Internet use

(Shapira et al. 2000; Caplan 2005). The socio-cognitive model of Internet addiction (LaRose et al. 2003) offers a similar explanation and proposes that because Internet use can be psychologically rewarding, people are incentivized to continue using it. When combined with low self-regulation and high self-efficacy, habitual Internet use can develop, resulting in extensive social media usage. Finally, the social skill model (Caplan 2005) posits that people engage in social media activity because they perceive online social interactions more favorably than in-person, face-to-face interactions. Over time, this preference for online social interactions results in compulsive social media use. According to this model, people are more likely to have or develop this preference if they perceive themselves as lacking self-presentational skills (McKenna and Bargh 1999) or if they believe that "one is safer, more efficacious, more confident, and more comfortable with online interpersonal interactions and relationships" (Caplan 2005, p. 629).

These theories are useful in elucidating the "how's" and "what's" of social media, thus shedding light on the precursors and outcomes associated with social media use. However, they are inadequate in addressing the fundamental "why" questions, such as why human beings would be so amenable to social media in the first place or why excessive social media use can be harmful. In the following sections, we apply an evolutionary analysis to social media and describe how social media interacts with our evolved psychology, which in turn gives rise to its various effects on human behavior and well-being. In so doing, we also demonstrate how an evolutionary perspective can address fundamental questions associated with social media usage and its effects.

The Evolutionary Basis of Social Media Use and Effects

From an evolutionary perspective, human behaviors are the products of psychological adaptations that evolved to solve recurrent survival and reproductive challenges. Because humans rely heavily on social groups to meet their survival and

reproductive needs, individuals who get ousted from their groups face a tremendous survival disadvantage. As such, our psychology is adapted to facilitate behaviors that increase the likelihood of social inclusion and reduce the likelihood of social exclusion. The need to belong and desire for social acceptance may have evolved in humans to motivate affiliative behaviors and increase the likelihood of being included in groups (Buss 1990).

In order to enact adaptive behaviors to maintain or protect inclusionary status, humans may have also evolved a social monitoring system to detect cues signaling important social information, such as indicators of social approval or rejection (Pickett and Gardner 2005), which then trigger the psychological mechanisms responsible for producing appropriate adaptive behavioral responses. For example, self-esteem has been argued to be an internal gauge that signals how well liked or socially accepted a person is (Leary et al. 1995). When people detect that they have been socially rejected or excluded, their self-esteem correspondingly decreases. This aversive psychological experience adaptively activates compensating behaviors that may appear aimed at restoring self-esteem on the surface, but are more fundamentally aimed at repairing their social acceptability. Hence, the social monitoring system plays a critical role in detecting social information that conveys the status of social relationships and acceptance in social groups.

Social Media Hijacks Our Evolved Social Psychology

People's amenability to social media can be understood in terms of social media's function as an outlet for people to satisfy their evolved social needs. In a small ancestral village, events that occurred to a person would be maximally only three degrees of separation away from anybody else in that village (Christakis and Fowler 2009). Thus, any social information was likely to be self-relevant and important because of the small size of a village community, and we likely evolved to be highly sensitive to all kinds of social information (Yong and Li 2018). Social media, in particular, social networking sites such as Facebook,

MySpace, and LinkedIn, capitalizes on our tendency to assume that all social information is important. The vast amount of readily available social information on social media triggers people's evolved psychology to attend to such information and can cause social media users to spend copious amounts of time on social media. For instance, a study found that students spent more time observing content on Facebook rather than actually posting content (Pempek et al. 2009), thus suggesting that social media sites feed people's need to monitor social information.

Because of the need to rely on others for survival, early humans evolved to instinctively forge ties with others, and the careful (and successful) maintenance of strong ties was also likely possible given the small population of an ancestral village (approximately 100–230 people; Dunbar 1992). Thus, the need to belong and build relationships can motivate people's social media use (Nadkarni and Hofmann 2012). Social media sites enable users to form new friendships, maintain existing relationships, and interact with other people in a wide variety of ways with unprecedented convenience. As such, Facebook users aged 18–24 years old have, on average, more “friends” than an ancestral person would have encountered in an entire lifetime (Blease 2015). Due to the large size of online social networks, the ties between social media users and most of their connections are typically latent (i.e., individuals only have passing awareness of each other) or weak (i.e., individuals only seek each other occasionally for information or other forms of trivial support; Ellison et al. 2011). Yet, we likely evolved to treat our large but weak online social networks with as much attention as ancestral humans would have given their strong but small social networks. Thus, the amount of effort put into maintaining a social network of the size faced by our ancestors may have been more manageable than that faced by modern humans, causing social media users to spend an unnecessarily substantial amount of time and effort upkeeping their online connections.

Social media also capitalizes on our evolved need for social validation. Social media sites often incorporate the use of “like” buttons as a means

for users to quickly provide social feedback. Because such likes directly reflect social approval, people can rely on likes to monitor their inclusionary status and how socially accepted they are. A study that experimentally manipulated the number of likes received by participants for a personal photograph found that people who received a greater number of likes reported higher levels of self-esteem (Burrow and Rainone 2017). The ostensible display of the number of followers one has also serves as another proxy for social inclusion and popularity. This is further glorified by Instagram's coveted "blue tick," which is usually conferred to users with a substantial amount of followers and influence, such as celebrities, influencers, and politicians.

One commonly cited reason for the extensive use of social media is the "fear of missing out" (FOMO; Przybylski et al. 2013), which is defined as a preoccupation over whether others might be having rewarding experiences in one's absence. As such, people can feel compelled to stay connected on social media to find out what others are doing. This apprehension is arguably indicative of the social monitoring system at work, whereby social media users constantly monitor for cues to social inclusion or social exclusion from network acquaintances. FOMO has been found to be associated with the activation of the right middle temporal gyrus, a brain region involved in the processing of social inclusion cues (Lai et al. 2016), thus suggesting that individuals are on the lookout as to whether they are still included in their social groups.

The foregoing analysis shows that our proclivity toward social media use and vulnerability to overuse can be understood within the context of our evolved psychology to socially belong and monitor for social information. As opposed to other theories that implicate addiction or other forms of psychopathology, the evolutionary perspective instead suggests that because social media exploits common features of normal human psychology, obsessive social media use can also occur in well-adjusted, psychologically healthy individuals, thus accounting for its widespread contemporary use.

Harmful Outcomes of Social Media Use

The evolutionary approach can also be used to shed light on the harms that may emerge from excessive social media activity and why, despite these harms, people still persist in using social media.

Through comments or likes, social media presents users with opportunities to quickly gauge social approval. However, people who post content on social media are exposed to both the possibility of receiving many likes as well as the possibility of receiving very few or no likes at all. As people tend to be more sensitive to negative information, social media users can inadvertently be more affected by not having enough likes compared with having enough likes, resulting in poorer mood and lowered self-esteem (Burrow and Rainone 2017). The desire to gain likes and other positive feedback may also prompt an obsession with the sharing of content that leads to unhealthy self-image, such as photographs of oneself in skimpy clothing or engaging in sensational or scandalous activity, which may garner more attention (Chua and Chang 2016).

Social media can also induce envy and self-dissatisfaction in users due to social comparison. As social media users tend to carefully select and curate the things they upload on social media platforms, social media tends to portray only the most perfect aspects of people's lives, such as flattering photographs, nice holidays, and work success (Siibak 2009). Our evolved psychological tendency to crave and digest social information takes the information we see on social media seriously and makes us compare ourselves to those we see on social media. As social media sites continually present information about how good-looking others are or how well others are doing, avid social media users are apt to experience envy and dissatisfaction with various aspects of their own lives (Yong and Li 2018).

By being a source of more information than people are evolved to need, social media can also trigger excessive jealousy. Increased Facebook use has been found to be associated with elevated jealousy due to a feedback loop, whereby using Facebook exposes people to ambiguous information about their partner that they may otherwise not have known, which then motivates further use

to seek more information that may be unwittingly self-confirming (Muisse et al. 2009). Texts on social media are often ambiguous because they are devoid of emotional cues. For instance, a neutral message left by a man on a woman's public post on Facebook, such as "hey how r u," can be misinterpreted to be more flirtatious than it really is by the woman's jealous partner.

People still persist in their use of social media despite its deleterious effects. From an evolutionary mismatch perspective, this is unsurprising because social media represents a modern stimulus that efficiently hijacks our evolved psychological mechanisms, which are adapted to respond to stimuli in ancestral conditions (Li et al. 2018). Just as how our tastes for sweet things, which evolved to adaptively impel humans to eat fruits and other natural foods high in calories and nutrients, are now inducing people to ingest modern foods manufactured with high levels of sugars (e.g., candy bars, soda), likewise modern humans cannot help but continue responding to social media in the ways that they do, to their own detriment.

Conclusion

The use of social media in the modern world can be a puzzling phenomenon, especially if we consider that people continue to use and participate in social media activity despite its negative effects. The evolutionary approach, which considers how social media hijacks our evolved psychology for social belonging and monitoring, can facilitate a better understanding of the widespread use and effects of social media. This awareness of the fundamental mechanisms that underlie social media use can encourage future research on the factors that may regulate excessive social media use, such as users' social media network size or other offline activities that may engage people's need to belong in relatively healthier ways.

Social Neuroscience of Self-Categorization

Alexander Shkurko
Ulyanovsk/Nizhny Novgorod, Russia

Synonyms

Social neuroscience of social identity

Definition

The study of neural processes underlying representation of social group membership.

Introduction

Self-categorization is a cognitive process of perceiving both oneself and others in terms of collective entities (social groups or categories) rather than in terms of individual characteristics and personality. Development of new methods of the brain research allows studying self-categorization at the neural level. Self-categorization became one of the key issues in a new scientific discipline, social neuroscience, which is an interdisciplinary field of research on the intersection of neuroscience and social psychology studying neural basis and mechanisms of social cognition, emotions, and behaviors.

Self-categorization in Social Psychology

Self-categorization refers to social categorization, i.e., classifying individuals into social groups or categories, from an ego-centric perspective. This means that not only social world is classified and typified during social categorization but also that an individual is positioned in this social world and describes him/herself in terms of membership in specific social groups or categories such as ethnicity, race, gender, age, political preferences, family. The outcome of self-categorization is the formation of specific social identity, which is a part of the self-concept, representing knowledge and feelings of their group as well as its psychological value. Key theories of social psychology, namely, Social Identity Theory and Self-Categorization Theory (Turner and Reynolds 2003), treat self-categorization and social identity as the basis of intergroup relations and associated perceptions, attitudes, and behaviors.

During social categorization, individuals tend to focus on similarities within groups and differences between groups, thus maintaining and reinforcing group boundaries. Studies in social

psychology showed that individuals differently respond to social groups with which they associate themselves, i.e., ingroups, and all other, i.e., outgroups. These effects include asymmetrical responses to in- and outgroups at cognitive, affective, and behavioral level. Perceived group differences affect attention, memory, judgments, evaluations, empathy, motor predispositions, and allocation of resources. Social psychology treats these asymmetries as a source of many problematic aspects of intergroup relations such as prejudice, discrimination, intergroup conflicts.

Evolutionary, social categorization is considered as an important tool for social species. Living in collectives requires ability to make fast and accurate identification of social agents and infer their intentions. Establishing alliances is crucial for survival and the necessity to detect allies should lead to development of effective skills in social cognition. Affiliation with a group is necessary to satisfy social needs such as sense of belonging and self-esteem. Studies in primatology show that nonhuman primates have well-developed social cognitive skills and share basic predisposition to form and detect various social groups as well as form preferences for the members of their own group, the so-called ingroup favoritism.

The Social Neuroscience Approach to Self-categorization

Evolutionary significance of social categorization implies that the ability to effectively classify and automatically respond to different types of social objects must be supported by specialized biological systems and mechanisms: genetic, physiological, and neural. The progress in neuroscience provided social psychologists with new research tools to study social categorization. Among them, functional magnetic resonance imaging (fMRI) and electroencephalography (EEG) became the two most actively used. Whereas the first one helps to identify neural systems involved in various aspects of social categorization, the second one allows effective tracing the time-course of social cognitive and affective responses during social

categorization. Other research methods that can be used in social neuroscience of self-categorization include magnetoencephalography, transcranial magnetic stimulation, administration of “social” hormones such as oxytocin and testosterone, lesion studies, animal models, and some other.

The Brain Structures Involved in Neural Processing of Self-categorization

Studies in social neuroscience revealed several brain regions, which are especially important for social categorization and representation of social identity (Cikara and Van Bavel 2014; Molenberghs 2013; Shkurko 2013).

Amygdala, a part of the brain’s limbic structure, was initially associated with fear conditioning and fast negative response to the members of racial outgroups. Later studies showed that it can be selectively activated in response to ingroup member as well. Currently, the role of amygdala in social categorization is associated with the detection and emotional arousal in response of socially relevant stimuli. In different contexts, both in- and outgroups can be motivationally significant and evoke selective activation of amygdala.

Medial prefrontal cortex (mPFC), a frontal part of the cerebral cortex, is involved in several higher-order social cognitive processes which include mentalizing (taking the perspective of other individuals), processing self-relevant information, and cognitive empathy. Particularly, mPFC demonstrates greater activation in response to ingroup members and self-referential thinking as compared to mentalizing about outgroup members, thus supporting the view that social identity is a part of individuals’ self-concept. Extreme outgroups such as homeless people, on the contrary, may not elicit activation of mPFC during mentalizing tasks, thus indicating “dehumanization” of such social groups.

Anterior cingulate cortex (ACC) plays an important role in affective regulation. Specifically, parts of this brain structure were found to support affective empathy toward ingroup members and suppression of negative emotions in response to outgroup members.

Temporoparietal junction (TPJ) is important for mentalizing and may be involved in the construction of ingroup via perceived similarity with oneself and result in greater ingroup bias.

Fusiform gyrus (FG) and *fusiform face area* (FFA) are traditionally associated with perceptual expertise and sensitivity to facial stimuli, which are one the most important source of socially relevant information. Activation in FFA is associated with the better memory for ingroup faces. This finding is consistent with the idea that self-categorization lead to greater attention and individuation of ingroup members. There is evidence that FG is flexibly involved in social categorization and is subject to top-down regulation of social stimuli perception (Freeman et al. 2010). Particularly, preexistent high-level knowledge of social categories may modulate perception of social sensory input.

The human reward processing system, which includes *ventral striatum* (VS), *dorsal striatum* (DS), and *orbitofrontal cortex* (OFC), is also involved in several aspects of social categorization. Being sensitive to social status information and representing the value of subjectively rewarding stimuli, these regions are important for situations in which group perception is associated with the differences in status or involved in competitive relations. For example, in the context of intergroup competition, VS is activated in response to outgroup failures or misfortune, thus indicating their subjective value (*schadenfreude*) and group-based modulation of empathetic responses (Cikara et al. 2014; Hein et al. 2014). Some studies show that OFC can encode the value of pro-social, cooperative behavior and thus can be involved in mitigating discriminating behavior.

Insula is believed to be a part of the “pain matrix” and is involved in processing negative emotions during social categorization, although its exact role and group selectivity is not clear. For example, left anterior insula was especially responsive to the pain of ingroup members. At the same time, other studies reported activation of the right insula in response to outgroup members and its role in modulation of discriminatory behavior toward them.

Identification of the brain systems involved in social categorization is mainly the result of using fMRI technique. However, studies of hormones become increasingly important in revealing neural mechanisms related to social identity and intergroup behavior. For example, a neurohormone oxytocin known for its role in social affiliation can be sensitive to group membership. Particularly, in the social contexts in which social identity is salient, oxytocin is associated with greater ingroup love (but not outgroup hate). Exogenous administration of oxytocin and some drugs such as propranolol are considered as possible tools for interventions aimed at reducing intergroup conflicts and other negative consequences of social categorization.

Neural Processing of Self-categorization: Key Findings

Contemporary social neuroscience provide evidence supporting several important conclusions on the neural processing of self-categorization and social identity:

1. Social groups are represented in the brain differently. Those groups with which an individual identifies him/herself evoke different neural responses as compared to other groups. Moreover, different ingroups and outgroups can also evoke different neural responses.
2. The social brain evolved to support fast and effortless reaction to different social groups. Both EEG and fMRI studies showed that the brain can detect group membership of perceived social agents within first two hundred millisecond, i.e., classify them automatically.
3. Asymmetrical neural responses to ingroups and outgroups were found in regard to many different cognitive, affective, and behavioral domains: visual perception, attention, memory, mentalizing, empathy, motor predispositions, judgments, evaluation, and economic decision-making.
4. Effects of social categorization on perception, cognition, evaluation, and behavior occur even when group boundaries are based on trivial situational and arbitrary criteria, i.e., in the so-called “minimal groups.” These effects include better face recognition of ingroup members, biased judgments, and ingroup favoritism. This means that the social brain evolved not only to facilitate fast identification of social groups but also to support cognitive biases, prejudice, and discriminatory behavior in favor of the group to which individuals belong.
5. Despite the importance of automatic neural responses supported by the limbic system, social categorization in humans is subject to cognitive and affective regulation processed by evolutionary more recent prefrontal cortical areas of the brain. Moreover, there is evidence that neural processing of social categorization is bidirectional and combine continual representation of actual perceptual stimuli, particularly in FFA, with higher-order discrete categories represented in other cortical regions, particularly OFC (Freeman et al. 2010).
6. The neural representation of social identity and group-related effects can be flexibly tuned and reconfigured in response to changes in the context, social roles taken by individual, and tasks performed. When a new identity becomes contextually salient, other identities (e.g., race) even evoking automatic biased responses can become overridden and their negative effects can be diminished.
7. Neural processing of self-categorization and social identity is culturally conditioned. Individuals from different cultures, e.g., individualistic and collectivistic, demonstrate differences in the representation of ingroups and various aspects of ingroup bias. For example, collectivists more than individualists involve activity in mPFC and left TPJ during representation of the personal self thus probably indicating a greater role of social identity and perspective-taking in the construction of the self (Sul et al. 2012).

Conclusion

The human brain evolved to effectively manage complex social relations and support group-based

thinking, emotions, and behaviors. Studies in social neuroscience showed that there are no single neural system which could be directly associated with the representation of social identity and self-categorization effects. Instead, multiple systems are involved in various aspects of social categorization in a flexible and context-dependent manner. As a result, the brain is tuned for both biased and discriminatory reactions to the members of the social groups, and cognitive mechanisms supporting egalitarian responses and strategic manipulations with social identities to better fit the situation and the task needs.

Social Outcomes and Sex Ratio

Sebastian Schnettler and Andreas Filser
Department of Social Sciences, Carl von Ossietzky University of Oldenburg, Oldenburg, Germany

Synonyms

[Behavioral adaptations to variation in human sex ratios](#); [Consequences of imbalanced sex ratios](#)

Definition

Social outcomes that are associated with variation in the relative share of men and women active on a mating market.

Introduction

An imbalanced sex ratio, that is, a male or female surplus on the mating market, may occur due to sex-selective fertility, mortality, or migration dynamics (Dyson 2012). For instance, in parts of Asia and Europe, continued son preference, fertility decline (in the case of China's one-child policy legally prescribed), and the spread of ultrasound technology facilitating sex-selective abortions are seen as the main contributors to a trend of demographic "masculinization" (Guilmoto 2009; Hudson and Den Boer 2005). In 2004, for instance, the nationwide average for the sex ratio at birth was at about 120 and 112 boys per 100 girls born in China and India, respectively. In some provinces it was even higher, thus clearly exceeding the ratio of about 105 boys per 100 said to be the "natural" sex ratio (Guilmoto 2009; Hudson and Den Boer 2005). As the cohorts affected by such imbalanced sex ratios at birth have been maturing and reaching adulthood, many young men – sometimes referred to as "bare branches" – have found it difficult to find a partner (Hudson and Den Boer 2005). Another instance is a clear pattern of sex-selective migration that has been documented for regions across Europe: Women are more likely to migrate from rural areas to the cities for better educational and occupational opportunities than men, resulting in a wide range of sex ratios across these regions (Filser and Schnettler 2018; Wiest et al. 2013). Yet, in other cases of *international* migration, migration patterns are sometimes dominated by men or don't show a clear sex-selective pattern (Dyson 2012).

Scholars from various disciplines, including evolutionary biology and psychology, family sociology, and demography, have argued for a potential link between sex ratios and a range of social outcomes. Empirical research in these only partially overlapping literatures has demonstrated such associations with multiple such outcomes

and on various geographic scales (Dyson 2012; Filser and Schnettler 2018; Guilmoto 2009). Social consequences that have been linked theoretically or empirically with sex ratios include couple bargaining, economic decision-making, female labor force participation, female pubertal maturation, fertility and fertility preferences, gender roles, marriage and relationship dissolution, as well as sexual norms and preferences (e.g., Bauer and Kneip 2013; Dyson 2012; Filser and Schnettler 2018; Gay and Boehnke 2017; Guttentag and Secord 1983). Yet arguably the most severe consequence that scholars predict and one that has received most scholarly and public attention is that male-biased sex ratios may contribute to higher rates of violent crimes and prostitution, and regional destabilization (Dyson 2012; Filser and Schnettler 2018; Hudson and Den Boer 2005; Schacht et al. 2014). However, the variety of disciplines involved in sex ratio research has resulted in a fragmented and sometimes contradictory literature.

Potential Mechanisms

Why should any consequences of imbalanced sex ratios and social outcomes be expected at all? The main argument is that the surplus of one sex on the mating market increases competition among individuals of the abundant sex and allows individuals of the scarcer sex to be more selective in their partner choice. In addition, dyadic power in an existing relationship is considered to be affected by sex ratio-dependent opportunity costs. Thus, whether an individual decides to cater to a partner's preferences or to end the relationship is co-determined by the number of alternative relationships. The numerical balance of men and women on the mating market in turn affects this number of alternatives. A favorable sex ratio, i.e., a shortage of one's own sex, makes finding an alternative partner more likely than an unfavorable shortage of individuals of the opposite sex. Following this logic, an argument can be made, that the prevalence of any behavioral adjustment that would allow individuals of the abundant sex to improve their chances on the mating market, or to retain their partner in an existing relationship,

might be associated with sex ratio imbalances (Filser and Schnettler 2018; Guttentag and Secord 1983).

Whereas this supposed relationship, on a very coarse level, seems to be agreed upon by most authors, there are considerable differences when it comes to detail. In fact, this leads to diametrical predictions with regard to the purported association between sex ratios and violent crime: Some authors propose that an increase in the sex ratio should go along with an *increase* in violent crimes. Others argue that an increase in the sex ratio should go along with a *decrease* in violent crimes. On both sides of the argument, authors draw on parental investment theory (► [“Parental Investment and Sexual Selection”](#)): Due to a differential in (potential) reproductive variance between males and females, sexual selection is thought to have favored a stronger preference for long-term mating and signals for parental investment in females as compared to men. Now the two sides of the argument differ in their emphasis on what follows from this. On the one hand, scholars who propose a positive association between sex ratios and violent crime argue that females, due to their comparatively higher selectivity in partner choice, are to be considered a scarce resource. This in turn favored mate seeking and competitiveness in males. Increasing sex ratios are thus expected to imply more (violent) mating competition. On the other hand, scholars who propose a negative association emphasize that in a high sex ratio context males should compete for female partners by meeting female preferences, that is, by signaling long-term mating and parental investment potential. In this view, violence appears to be a counterproductive strategy for finding a mating partner, because women might choose men with resources over physically dominant males (Schacht et al. 2014).

Methodological Issues

If the theory on sex ratio outcomes is so divided, has at least empirical research been able to settle this issue? Not quite! In fact, some authors find a positive, some a negative, and some a null-finding with regard to the association of sex ratios and

violent crimes (Filser and Schnettler 2018; Schacht et al. 2014). A number of methodological and data-related issues of previous studies may contribute to this inconclusiveness: Some studies compare sex ratio associations between countries which implies that entire countries are operationalized as potential mating markets. This may, however, be inappropriate given a considerable within-country variation in sex ratios (e.g., between rural and urban regions) in many countries. In addition, almost all studies correlate sex ratios and social outcome indicators on the aggregate level, thereby risking an ecological fallacy. Most research has also been limited by cross-sectional research designs. Longitudinal research designs would improve the ability to establish a potential causal link between sex ratios and social outcomes (Filser and Schnettler 2018).

Conclusion

Imbalanced sex ratios have been linked to a wide variety of social outcomes. Of these purported associations, only few have received as much attention as the potential correlation between sex ratios and violent crimes. Nevertheless, theoretical predictions and empirical evidence of this association remain contradictory.

Overall, our understanding of consequences of sex ratio imbalances is still emergent even for relatively well-studied potential outcomes of imbalanced sex ratios. For instance, a number of studies have addressed the association between sex ratios and mating behavior, yet empirical evidence seems inconclusive as well (► [“Sex Ratio and Men’s Long-Term Mating”](#)). Therefore, it seems particularly premature to draw conclusions on associations of sex ratios with other social outcomes in cases where empirical evidence consists of a single or only a few studies. Thus, more research is necessary to substantiate which social outcomes are associated with sex ratios and how strong these associations are. This should include replication studies to test if the same associations hold with data from other social and cultural contexts, data sources, and research designs.

To maximize the insight of future studies, researchers should seek to follow a few

recommendations. Whenever possible, individual-level data should be used: For example, in the case of violent offending, data on individual-level offending should have priority over aggregate crime rates. Second, different operationalizations of mating markets should be tested and compared. How robust are findings to these different operationalizations? Finally, longitudinal research designs should be given priority over cross-sectional designs. After all, if the sex ratio can be considered a cause of a particular social outcome, its measurement needs to precede the measurement of the social outcome of interest. The issue of migration illustrates this well: Sex-selective migration affects sex ratios, but imbalanced sex ratios may themselves drive sex-selective migration (Dyson 2012; Wiest et al. 2013). To disentangle such a potentially bidirectional causal link cannot be resolved with cross-sectional observational data.

In addition to studies that document statistical associations, ideally with improved research designs, research is needed that closely focuses on the potential mechanisms involved therein. Little is known, for instance, about if and to what degree local sex ratio imbalances on mating markets are actually perceived as such by individuals active on those markets and how this affects their behavior (Filser and Preetz 2019). Although some studies have tested the sensitivity of individuals to sex ratio variation in materials presented to participants in a lab setting, little is known about the external validity of these findings: Does this sensitivity, for instance, only apply to micro-situational contexts (e.g., the sex ratio in a room, at a party, or in a business meeting), or does this sensitivity generalize to larger contexts like marriage markets? A recent study compares subjective and objective sex ratios at various geographical scales and with different operationalizations of the sex ratio. It finds no association between the two (Filser and Preetz 2019).

The distinction between perceptions of sex ratios on a situational versus larger context is relevant with regard to the underlying mechanisms. A common assumption is that individuals do in fact perceive if they are on a highly competitive mating market and adjust their behavior accordingly, e.g., by acting more aggressively or

by adjusting more strongly to the (perceived) preferences of potential mating partners (Schacht et al. 2014). Another potential explanation would see individuals more or less ignorant toward sex ratio imbalances in their respective regions. However, these imbalances would imply that individuals are selected with a certain probability into social situations that are themselves characterized by a similar numerical imbalance between men and women. Only in these situational contexts would individuals actually perceive the (situational) sex ratio imbalance, which could in turn induce behavioral responses. Taylor (2014) showed experimentally that the co-presence of another man increased cortisol levels in male participants when solving a competitive task. This finding may be interpreted as preliminary evidence that (male) individuals respond to differences in the sex composition of their immediate social context.

Definition

In most mammalian species including humans, Social Play describes playful activities, such as tumbling, chasing, and making faces, among two or more individuals that support the development of mutually beneficial connections between them.

Introduction

Social play involves a variety of playful activities that are directed towards other people (Pellis and Pellis 2007), involving at the very least two interacting players exhibiting behaviors that highlight the context of the relationship between them (Gleason 2017). For young primates, social play is the stage that involves making use of their peers for the purpose of social exploration characterized by at least two basic social play patterns: rough-and-tumble play or contact play, e.g., wrestling, pulling, biting, and rolling, and, approach-withdrawal or noncontact play, i.e., taking turns swiftly chasing back and forth each other across an area, with regular interchange between the roles of leader and follower (Harlow 1969). Some additional expressions of social play in both humans and animals include chasing, play-fighting, and peek-a-boo while more cognitively sophisticated forms found largely in human children include sociodramatic and construction play (Graham and Burghardt 2010).

Social Play – An Overview

To engage in social play, a very common mammalian activity (Durand and Schank 2015), at least two individuals are needed which are commonly from, but not limited to, the same species (Graham and Burghardt 2010). Another definition views social play as a “state of engagement” where both partners alternate behaviors that they modify each time based on each other’s reactions in a successive order, hence, these behaviors meet two criteria where on one hand they are alternating and contingent on each other and on the other hand they appear to be nonliteral or abstract

(Garvey 1974). For example, in play-fighting the attacker might intentionally let his guard down, something unlikely to happen in a real fight, so that the defender can counterattack (Pellis et al. 2010).

When at least two children are alone in a room together there are four possible “play” states that can take place: (a) social non-play (a joint activity that does not involve play, e.g., work together to fix a toy that was broken), (b) non-social non-play (e.g., even though they are in the same room, they explore independently), (c) non-social play (e.g., play acting imaginative scenarios independently, e.g., one is playing the doctor and the other is playing the cook), (d) social play (collaboratively playing together, e.g., hide and seek) (Garvey 1974). There is additional support from behavioral studies and observations with juvenile rats which differentiate social type behaviors as between related and unrelated to play (Vanderschuren et al. 1997). According to Burghardt (2011), there are five criteria that describe play behavior, which state that: “Play (1) is incompletely functional in the context in which it appears; (2) spontaneous, pleasurable, rewarding, or voluntary; (3) differs from other more serious behaviors in form (e.g., exaggerated) or timing (e.g., occurring early in life before the more serious version is needed); (4) is repeated, but not in abnormal and unvarying stereotypic form (e.g., distressed rocking or pacing); and (5) is initiated in the absence of acute or chronic stress.”

One of the most common forms of social play found in animals is rough-and-tumble play also called play-fighting and accounts roughly for 10% of play activities in human children (Pellis et al. 2010). Rough-and-tumble play or play fighting is a competitive form of social play with the most amount of research (Pellis and Pellis 2007). The differences between play-fighting and actual fighting lay in five specific details: (a) during play-fighting there is no competition for vital resources, (b) the players show restraint and avoid doing serious, if any, harm, (c) there are reversing roles between the two players of attack, defense, and counterattack, (d) the act brings both parties closer together, and (e) for humans and many other species, play is communicated

through distinctive signs from the face and body (Pellis et al. 2010). Despite the similarities to other sexual or aggressive behaviors, these differences that describe social play postulate it a distinct category of behavior and not only a precursor of adult type behaviors (Vanderschuren et al. 1997).

According to Bekoff (2001), because of the similarities with aggressive behaviors, play needs to be communicated to the social partner beforehand in an effort to reach a consensus on the activity avoiding the chance for it to be interpreted as a threat (e.g., perceived as an intention to fight or predation). Exaggerating normal behavior or the use of plain old smiles and giggles can reflect the intent to play and that the presented play activity or behavior is neither threatening nor meant to be taken literally (Garvey 1974). What is more, Bekoff (2001) expresses the value of “role-reversing” (where the dominant individual voluntarily behaves in a manner unlikely to transpire in real events, e.g., rolling over) and “self-handicapping” (e.g., biting less intensely) in social play to balance the scales of power and make their intention of continuing to play known to their partner. These actions have the added benefit of allowing juveniles the opportunity to practice and learn valuable skills that would otherwise cost them their survival if not properly mastered (e.g., practicing counterattacks during play-fighting that will be extremely valuable in a real fight happening in the future).

Bekoff (2001) further proposed that in a sense social play may have facilitated the evolution of social morality, specifically the value in playing fairly during a game where innocence in play and forgiveness of any transgressions prevails over competition while allowing to safely practice cooperative skills – especially to younger players still on the learning curve and not thus far perceived as anyone’s adversary. Through social play, rules for social conduct have evolved, practiced, and learned to monitor acceptable and unacceptable behaviors and establish the grounds for social morality to be generalized across other real-life situations. Also, this social conduct assists the development of trust placed from one partner to another as well as the development of a preference to finding partners that play fairly quite possibly extending to represent the integrity and stability of

a group of individuals. In addition, the author explains that for the duration of the “socialization period,” a short but critical time interval during the early development, self-responsibility about one’s own welfare is waived so that social skills development happens at a faster pace while social play deprivation during this critical time period can result in unwanted consequences.

Eckerman et al. (1975) separated 60 children in three different age groups; 10–12, 16–18, and 22–24 months of age (10 pairs each) and observed them during a novel play setting with both mothers and peers present. They found that children between 10 and 12 months of age preferred solitary play; from 16 to 18 months of age, children chose to play more with their mothers; and from 22 to 24 months, children preferred to play more with their peers. In other words, similar to Harlow’s (1969) reports with young primates as age increases and social play interaction begins to involve more people, the children’s preference turns to their peers rather than their parents. Additionally, Eckerman et al. (1975) observed that by the second year of life, children’s behaviors towards other children closely resembled those cultivated through contact with significant adult figures in their lives such as “smile, laugh, vocalize and gesture to one another, show and offer toys, imitate each other, struggle, and engage in reciprocal play” rather than those learned during play with inanimate objects. Possible explanations behind these sex differences in social play may very well lay in the different prenatal hormonal exposures between males and females (Meaney 1988) or the aftermath of the many discrepancies different cultures have between them (Michael and Crook 1973). Despite the fact that there are relatively few data regarding the survival and reproductive benefits of social play, it is widely accepted that both short-term and long-term benefits among different age groups, species, and sexes deviate (age and sex differences exist even within the same species) (Bekoff 2001). Additionally, Meaney et al. (1985) reported a large number of studies to illustrate that sex differences do exist in mammalian species’ social play, yet, the authors caution that these differences are not universal for all species. For instance, they

provided research-based evidence from several studies which indicated that males prefer and engage more intensely in play-fighting than females even though their play is not qualitatively different; during chase-play, males tend to be the most frequent chasers and play-mothering (e.g., play acting with baby dolls) is far more prominent in female social play.

Social competency’s development is favored through the play-fighting interaction (Pellis and Pellis 2007) and social play may represent an extension of a social learning process in young mammals where they learn and practice new skills with their peers (Meaney 1988). Evidence suggests that autistic children can demonstrate successful social adaptation by incorporating their thematic ritualistic activities (i.e., repetitive behaviors) in social play interactions with their siblings, leading to social skills and affect improvement sustained to at least a 3-month follow-up measure (Baker 2000). Durand and Schank (2015) proposed a theoretical model where social play evolved because it allows juveniles to practice cooperation for a common goal and retain this skill as adults. However, they stress that for it to be adaptive, the potential fitness costs of social play, such as increased risk of predation, injury, energy, and foraging loss, must be significantly less than the long term benefits.

Social Play Interactions During Childhood

A critical developmental stage of childhood during the preschool years (before the age of 6) involves building a strong foundation of social competence through the initiation and maintenance of positive social interactions that facilitate later school success (Veiga et al. 2016). Even in the early stages of infancy, some form of social play begins from mutually playful interactions between newborns and their primary caregivers; however, once peer interactions commence this adult-infant social play synergy will eventually lose its precedence and be replaced by other children (Whaley 1990). Having said that, for infants social play begins from their first smiles and once

they are more communicatively adept it takes the form of babbling and cooing with their primary caregivers which empowers them to learn social rules through an adult-infant socialization and cultivate essential skills such as turn taking and role repetition (Frost et al. 2011, pp. 111–112).

Frost et al. (2011, pp. 151–152) defined six categories of observable social play behaviors based on the work of Parten (1932) that describe the development of social play in preschoolers. These categories include: “unoccupied behavior” – child is not playing but is mobile, active, and observes the room; “onlooker behavior” – the child is not playing and mostly observes his/her peers playing and may occasionally speak to them; “solitary play” – around 2–3 years of age, the child plays with his/her own toys by himself but does not engage other children and uses different toys than the other children; “parallel play” – the child uses the same toys as other children and plays beside but not with them; “associative play” – children play together in a common activity without sacrificing individual interests for a common group goal; and “cooperative play” – group play characterized of shared goals that are negotiated and comparable to adult situations. Additionally, they emphasize that children may progress in and out of these stages at a faster pace because contemporary child care is more advanced and readily available than the early 1930s.

According to Veiga et al. (2016), there are distinguishable variations and patterns that can be seen while observing children play, e.g., “children jump, use objects to facilitate pretend play, chase one another, pretend to be someone else and so on,” which can be further separated into four distinctive forms of play: fantasy play (begins around the age of two and involves playing with an object using imaginative thinking rather than the objects’ actual properties), role play (begins around the third year of life and involves play acting imaginative scenarios with peers) – both described as an extension of pretend play, and exercise play (starts during the first year and increasingly peaks during the fifth year of life and involves the child playing using motor skill-

based activities such as running or hopping) and, finally, rough-and-tumble play (peaks in frequency around 6–10 years of age and involves behaviors that may appear aggressive, such as chasing or wrestling, but in the context of play are socially important) – both described as an extension of physical play. Furthermore, there are different relationships between different types of play and different cognitive abilities; e.g., group pretend play promoted increased use of adjectives and prepositions in children’s speech in contrast to solitary or dyadic play, while tabletop toys decreased children’s performance on creativity tasks conceivably because they are usually played in solitary or in pairs and they do not favor creative thinking (Holmes et al. 2017).

Adults and siblings offer different supporting roles during play activities with children on the grounds that adults provide structured play activities with increasing difficulty, much like a scaffolding, that allows children to practice and develop more complex play whereas siblings provide a play partner for the toddlers where they can use and master the skills they have developed (Frost et al. 2011, p. 113). Nevertheless, children often participate in social play with seemingly no one present in the room with them. Gleason (2017) elaborated on the unique ability of humans due to their highly evolved cognitive functioning to reap benefits from social play through the act of imagination and fantasy alone. The author explained that children play with their imaginary companions to practice skills, experience positive and negative emotions, experiment and rehearse real life events in a relationship, with no considerable risks to their well-being, leading to a more adaptive social development. Instead of only playing with real partners, children gain the added advantage of being able to create a personally customized partner capable of suiting their needs which opens the door for higher social competence, emotional regulation, and interpersonal skills development. What is more, the author suggested that from an evolutionary standpoint, imaginary companions cannot be explained from having benefits to evolutionary fitness since not all children create them and yet they typically develop the necessary social skills to

form healthy relationships. In turn, considering that usually children use imaginary companions in direct relevance to relationships with their significant others, imaginary companions are probably an adaptation by-product from the evolution of imagination and the highly evolved neurobiological systems that promote relationship formation.

The choice of play materials, ranging from toys meant to be played alone to toys that are best utilized with the company of others places a significant impact to children's social behaviors (Quilitch and Risley 1973; Ivory and McCollum 1999). Providing either "isolate" or "social" toys to children of 7-years age average revealed a 16–78% preference in social play activities, respectively. This data illustrates that in order to maximize therapeutic benefits for children with social deficits (e.g., autism), practitioners could incorporate play materials into therapy that promote social and cooperative play (Quilitch and Risley 1973). Lastly, there are considerable developmental benefits for children engaging in social play, for instance, the storytelling of children was more enriched with verbs after the engagement in pretend play (Holmes et al. 2017), exercise play at the school's playground during preschool years facilitates later development of social competence (Veiga et al. 2016), and social play can accurately predict greater involvement in the outdoor preschool environment (Miranda et al. 2017).

Massively Multiplayer Online Games

A more recent form of social play emerged because of the popular use of the internet which equipped video gaming with a social component creating the growing phenomenon of Massively Multiplayer Online Games (MMOGs). Online social play causes a shift in the play setting from a real world to a virtual world setting that comes with its own set of challenges for the unacquainted and yet semantically interacting online players (Frost et al. 2011, p. 366). Ducheneaut et al. (2006) examined one of the most popular MMOGs, World of Warcraft (WoW), and indicated that even though MMOGs create a distinct

social environment at least in the early stages of the game, players use others as their audience for their achievements in the game instead of interacting in cooperative activities with them. Additionally, they suggest that MMOGs act as a "virtual Skinner box" where the player's actions are reinforced getting them hooked to the online game, making WoW an excellent example of how operant conditioning coupled with a social environment that emphasizes success versus failure can in fact become highly addictive. Massively Multiplayer Online Role-Playing Games (MMORPGs) have many features similar to single player games (Ducheneaut and Moore 2004) yet their social nature enables players to experience collaborative activities that hone their teamwork skills (Cole and Griffiths 2007) and rewards them by seeking and gaining reputation within a virtually constructed social community (Yee 2002).

A recent study found that adults aged over 55 years were able to develop meaningful relationships with their online World of Warcraft friends. However, their difficulty was to extent this online friendships and incorporate them into their real lives, possibly because of the long distance between them or a general difficulty to transform online friendships to real life ones (Zhang and Kaufman 2017). In addition, research into MMORPGs revealed that for people who are uncomfortable with parts of their self-image (e.g., appearance, gender, sexuality, age, etc.), the social environment created by MMORPGs can facilitate their ability to express genuinely and additionally provide them with a great opportunity to create lasting and meaningful friendships or partners (Cole and Griffiths 2007). This evidence may suggest that MMOGs are the next step of social play evolution where children and adults could practice basic skills of social interaction safely and at a low personal cost in a virtual world.

The Neurobiology of Social Play Behavior

Observational studies indicate that generally species with more developed forebrains exhibit more

frequent and complex forms of play (Pellis et al. 1992). Social play possesses significant merits in social development and some of its numerous functions illustrated by experiments using play deprivation include: social group organization or building ties between group members, to facilitate the development (on a cognitive level) of the ability to express and understand communicative signals between conspecifics which may in turn improve their ability to cope with social conflicts, and offer an opportunity to practice a variety of behaviors in a sequence in an effort to find out the ones that are most compatible to each other and eventually form advanced combinations (Vanderschuren et al. 1997).

Characterized by its inherent reward value, and because the power reward has positively reinforcing behaviors, social play can act as a well-used behavior learning incentive in animal studies (Vanderschuren et al. 1997). On account of this existing biological reward system which is influenced by social play behaviors, social play is expressed differently based on the pleasure and motivation experienced during the activity (Achterberg et al. 2016). Survival of the species depends on behaviors that are considered as naturally rewarding some of which include feeding, drinking, and sexual reproduction (Vanderschuren et al. 1997).

Motivation and incentives in social play are affected by dopaminergic neurotransmission (Achterberg et al. 2016) which is concurrent with research showing that the rewards gained from social play behaviors is underlined by an activation of the opioid and dopamine systems in the brain (Vanderschuren et al. 1997). In conjunction with this, research-based evidence illustrate that social behaviors increase after opioid drug treatments; however, social play is not guaranteed to increase from the stimulation of dopaminergic neurotransmission even though forebrain dopamine levels appear to increase during social play activities (Vanderschuren et al. 1997). Achterberg et al. (2016) examined the different effects of dopaminergic and noradrenergic signaling using an operant conditioning task and two psychostimulant drugs (methylphenidate and cocaine) on the social play behaviors of rats

and found that while dopamine acts as a stimulant in social play's motivation, it shows no influence over its expression; however, noradrenaline affects negatively the motivation and alters the expression of social play behavior. Evidence such as these indicates that social play is an independent category of behavior not only because of distinctive behaviors found only in such an engagement but because of specific neurobiological pathways triggered during social play (Vanderschuren et al. 1997).

To investigate the neural mechanisms during play, intact and decorticated rats were compared, indicating that those with removed cortices attacked and defended during play-fighting as frequently as their intact or decorticated pairs, hence a subcortical mechanism's involvement was proposed (Pellis et al. 1992). Pellis et al. (2010) discussed evidence of several studies to show the effects of the subcortical structure, amygdala, on regulating social behavior. They argued on research showing that play-fighting frequency as well as social recognition is impaired in rats with amygdala damage and that organisms with larger amygdala exhibit more play behaviors. They further explain that amygdala's role in monitoring fear and impulses during play fighting is essential since an animal's fear can prevent it from accepting another conspecifics' intention to play and minimizes social contact or inhibits them from controlling their impulses making them for unreliable play partners. Conversely, there is another perspective which views that a larger brain affects the production of more complex forms of play indirectly by extending the period of development and growth allowing for more play opportunities to occur (Pellis et al. 1992). In addition, there are some implications of mirror neurons firing when individuals share their intentions to partake in a social interaction (e.g., play), but it still warrants more research (Bekoff 2001). Lastly, some alterations of the amygdala have been shown in autistic people, which might offer an explanation for the difficulties they face with social contact consequentially causing individuals with autism to demonstrate poor social play (Pellis et al. 2010).

Conclusion

In response to social play's positive impact on social and cognitive development (Achterberg et al. 2016), evolutionary forces may have facilitated through positive selection the continuation of genes coding for a predisposition in the human species to engage in social play activities to increase fitness (i.e., individual reproductive success that also reflects the adaptation degree of an organism to its habitat) and therefore improve chances of survival. For instance, similar to primates' rough-and-tumble play, young human children engage in this type of social play with similar patterns since it increases chances of survival by enabling them to experience the sensation of being the dominant individual which in turn endorses self-confidence in future social interactions (Frost et al. 2011, pp. 150–151). Some other benefits of social play include advanced language abilities in children (Holmes et al. 2017) as well as opportunities to foster their creativity (Frost et al. 2011, p. 163).

Even though there are significant findings from several studies about the many benefits of social play, there are important limitations in the applicability of the results. Not surprisingly, most research on social play, especially in play-fighting, is carried using nonhuman animals that are most often of the rat species, mainly because of the practical (Pellis and Pellis 2007) and ethical limitations in conducting such experiments with human subjects which may in turn commend using caution when generalizing these same finding onto the human species. Additionally, it is worth noting that some researchers have advised that even if a child engages frequently in social play activities, it does not in any way guarantee a socially competent or maladjustment free adolescence (Frost et al. 2011, p. 194). Nevertheless, these limitations aim to increase awareness for more creative experimental testing and should not undermine the aforementioned developmental and evolutionary benefits of social play or the importance of informing adults and schools about the advantages in encouraging social play engagement in children.

Definition

The influence of the social status of a person within a group or society on cheater detection and memory for cheaters.

Introduction

Most human societies and primate groups are pervaded by social dominance hierarchies. It is

therefore plausible to assume that our cognitive system is shaped by selective pressures that require the individuals to adapt to the hierarchical organization of these social environments. Specifically, dominance theory (Cummins 1998, 1999, 2005) implies that the reasoning about social norms is affected by social rank. This hypothesis seems quite reasonable considering that social dominance hierarchies can be defined as a set of explicit or implicit social norms that define who is allowed to gain access to valuable resources (such as mates or food) and who is not. A social dominance hierarchy can only be maintained if the individuals in the group learn and follow the explicit or implicit rules that determine which behaviors are permitted, prohibited, or obligated for each individual, depending on the individual's social rank (Cummins 1998, 1999, 2005). This theory leads to the hypothesis that social rank may affect social reasoning (Cummins 1999) and, in particular, memory for cheaters (Mealey et al. 1996). This hypothesis needs to be empirically tested.

Dominance Theory

Following norms and helping others is one way to build alliances that help to gain and to maintain a high social rank in a group or society. High-ranking individuals have to share resources and have to fulfill reciprocal obligations to avoid losing important allies and, thereby, their status. Individuals with a low social rank, in contrast, may try to increase their limited access to valuable resources by cheating and by violating the social norms that deprive them of those resources. Given that the individuals with high social rank usually benefit most from the organization of the society, they are often responsible for enforcing the social norms that grant them privileged access to resources and for punishing the violation of these norms. Low-ranking individuals, in contrast, are lacking the resources to punish high-ranking individuals. Based on this reasoning, dominance theory (Cummins 1998, 1999, 2005) predicts that high-ranking individuals monitor the behavior of low-ranking individuals and are

highly vigilant against norm violations of low-ranking individuals, but not vice versa. In fact, the theory implies that cheater detection is a cognitive adaptation that serves to maintain social dominance hierarchies. A clear prediction that can be derived from this framework is that people should be more prone to detect the cheating of lower-ranking individuals in comparison to the cheating of higher-ranking individuals (Cummins 1999).

Although the above hypothesis is well grounded in a functional-evolutionary framework, it would not be right to uncritically accept this hypothesis based on plausible-sounding evolutionary arguments alone. Hypotheses in evolutionary psychology are tested in a similar manner as hypotheses in other areas of psychology and have to receive support from empirical tests before they should be accepted. It is useful to be aware that alternative hypotheses about the relationship between social rank and social reasoning are possible as well. A possibility that should be seriously considered is that social norms apply equally to high-ranking and low-ranking individuals. Consider, for example, the dictator game: In this game, the distribution of power is maximally unequal. One player, the dictator, receives a certain amount of money and has to decide how to split this money between him- or herself and the recipient. The recipient is entirely powerless and has to accept the offer of the dictator no matter how small. The dictator game can be viewed as a model of situations with extreme differences in social rank because the dictator has access to all of the resources and the recipient has nothing. Nevertheless, people generally judge an equal split between the two players to be most socially appropriate (Krupka and Weber 2013), suggesting that fairness norms are equally applicable to persons with high and low social rank. It is even possible to postulate that cheater detection should be higher when tracking the wrongdoings of high-ranking individuals (e.g., politicians with high political power), which would be directly opposed to the predictions outlined above. Some studies have indeed found positive associations between social rank and norm violations (Piff et al. 2012; but see Francis 2012). Despite this evidence to the

contrary, high-ranking individuals (e.g., professors) are often expected to be moral role models for lower-ranking individuals (e.g., students) and may therefore be judged by harsher standards. Accordingly, it is also possible to postulate that high-ranking individuals should show a noblesse oblige effect and should be more generous and forgiving against low-ranking individuals than vice versa (Fiddick et al. 2013). Hence, the hypothesis that people should be more vigilant against the cheating of low-ranking individuals in comparison to that of high-ranking individuals is a plausible possibility, but the opposite is equally plausible.

Is Social Reasoning Affected by Social Rank?

To test the prediction of dominance theory that people are better at detecting norm violations of lower-ranking individuals, Cummins (1999) used a deontic version of the Wason Selection Task. In the classical version of the task (Wason 1968), participants see four cards with a letter on one side and a number on the other (upper panel of Fig. 1). The visible sides of the cards show “A,” “B,” “4,” and “7.” Participants are required to select the cards they have to flip over to test the rule “If a card shows a consonant on one side, then

B	A	7	4
Borrowed the car	Did not borrow the car	Filled up the tank with gas	Did not fill up the tank with gas

Social Reasoning Affected by Rank (Mealey, Daoood, Krage, 1996), Fig. 1 Examples for the Wason Selection Task. In its original version (*upper panel*), participants see four cards and are asked: Which cards do you have to turn over to test the truth of the rule *If a card shows a consonant on one side, then there is an odd number on the other?* In the deontic version of the task (*lower panel*), participants are asked: Which of the cards do you have to turn over to see whether someone breaks the rule *If you borrow my car, then you have to fill up the tank with gas?*

there is an odd number on the other.” The correct solution is to pick the two cards that allow for a falsification of the rule (“B” and “4”). An interesting aspect of this task is that the majority of participants fail to solve the task correctly, suggesting that humans are not very good at (and not biologically prepared to) thinking about abstract logical problems. Another interesting observation (Cosmides and Tooby 2005) is that people are much better at solving the task when confronted with the more natural task of detecting cheaters that violate social rules such as “If you borrow my car, then you have to fill up the tank with gas” (lower panel of Fig. 1).

In Cummins’ (1999) deontic version of the Wason Selection Task, participants were required to test whether a resident assistant or a student showed compliance with the rule “If someone is assigned to lead a study session, that person is required to tape-record the session.” In a control condition, participants were told to imagine that they overheard a resident assistant’s or student’s statement “If I am assigned to lead a study session, I always tape record the session.”, and were asked to test the truth of the statement. Half of the participants were cued into the perspective of a resident assistant, and the other half were cued into the perspective of a student. Half of each group was instructed that they were checking on a resident assistant, and the other half were told that they were checking on a student. Reasoning was affected by rank, but only in the deontic version of the task. Participants were more likely to show evidence of a “look-for-cheaters” strategy when they were cued into the perspective of a resident assistant checking on students (65 % correct answers) in comparison to all other conditions (15–20 % correct answers). This confirms the prediction of dominance theory that high-status individuals are vigilant against norm violations of low-status individuals. Cummins (1999) interpreted these findings as evidence of a biological adaptation to social dominance hierarchies.

However, a plausible alternative to this interpretation is that Cummins’ (1999) manipulation had served as an implicit cue to monitor the compliance with the rule. Enforcing social norms and confronting norm violations of students is an

integral part of the role of a resident assistant, but not of fellow students. It seems possible that the effect was not due to differences in social rank but was rather due to the participants being aware of the fact that resident assistants are supposed to monitor the students’ compliance with norms. It seems therefore unnecessary to postulate a domain-specific mechanism for reasoning about social dominance hierarchies when the results can be attributed so easily to general learning mechanisms that allow individuals to acquire knowledge about the world, including knowledge about specific behaviors required by social roles. Therefore, additional research is needed to test whether these effects are indeed due to the influence of social rank rather than to the specific scenario realized in the study of Cummins (1999).

In a follow-up review, Fiddick and Cummins (2001) summarized several studies in which social status was unintentionally manipulated. Specifically, Gigerenzer and Hug (1992) required participants to take the perspective of high-ranking or low-ranking individuals when reasoning about rules. For example, participants were cued into the perspective of an employer or of an employee when reasoning about the rule “If an employee works on the weekend, then that person gets a day off during the week.” Fiddick and Cummins note that the findings reported by Gigerenzer and Hug (1992) do not provide consistent evidence of an influence of social rank on social reasoning. There was no significant effect of social rank on performance in the day-off problem (75 % detection of high-status cheaters and 61 % detection of low-status cheaters) and in a similar pension problem (64 % detection of high-status cheaters and 70 % detection of low-status cheaters). Only in one of three problems, the subsidy problem (“If a home owner gets a subsidy, then that person must have installed a modern heating system”), a significant effect of perspective was found (81 % detection of low-status cheaters and 59 % detection of high-status cheaters) although the subsidy problem was the problem with the least pronounced differences in social rank (house owner vs. environmental officer). However, the latter effect should not be over-interpreted given that Holyoak and Cheng (1995)

have obtained no effect of social rank using the same scenario.

Fiddick and Cummins (2001) used another variant of the Wason Selection Task in which they required participants to look for violations of the rule “If you pay for the gas, I’ll drive you to work.” Participants were either asked to take the perspective of a high-ranking individual (a boss) or of a low-ranking individual (an employee). The study demonstrated a high degree of intercultural variability in the effects of social rank on performance in the Wason Selection Task. In Germany, no significant effects of rank were obtained. In California, participants were better when monitoring the compliance of high-status individuals (70 % correct answers) than when monitoring the compliance of low-status individuals (45 % correct answers). This effect is in the opposite direction of what was predicted by Cummins (1999). The high cultural variability in the findings that has been identified by Fiddick and Cummins (2001) is challenging for the interpretation of the findings in terms of an evolutionary adaptation.

In another series of experiments, Fiddick and Cummins (2007) used a ledger task in which they confronted participants with different degrees of compliance on the part of the gas-paying partner and required them to indicate (1) how likely they would want to continue the car-sharing arrangement and (2) to what degree the arrangement was seen as fair or unfair. Again, participants were required to take the perspective of either a high-ranking individual (a boss) or a low-ranking individual (his or her employee). Participants cued into the perspective of a high-ranking individual were more tolerant of cheating than participants cued into the perspective of a low-ranking individual, which is again inconsistent with the original hypothesis that high-ranking individuals should be more, not less, vigilant against cheating of lower-ranking individuals (Cummins 1999). The results seem to be quite robust (Fiddick et al. 2013), but they are difficult to interpret. Fiddick and Cummins (2001) explained the discrepancy to earlier findings by arguing that the earlier findings (Cummins 1999) are about monitoring the compliance with social norms, while the

car-sharing scenario is about a reciprocal personal exchange. However, it is questionable whether these two can be clearly separated when reasoning about work-related activities that concern the employer-employee relationship. Somewhat puzzling, the noblesse oblige effect could not be attributed to an asymmetrical perception of the costs and benefits of the car-sharing arrangement for the employer and the employee, and it is unrelated to differences in income. When the individuals in the scenario were described as boss and employee, but not each other’s boss and employee, the effect vanished. This suggests that the underlying causes for the effect may lie in the specific relationship between a boss and his or her employee when performing work-related activities (paying the other person money for getting back and forth to work) rather than in differences between high-ranking and low-ranking individuals per se. It is an open empirical question whether these findings would generalize to other agreements between a boss and his or her employee and other asymmetrical social relationships.

Is Memory for Cheaters Affected by Social Rank?

Given that the research in the Wason Selection Task does not provide a clear picture, it seems necessary to test the influence of social rank on cheater detection in other paradigms. Fortunately, such evidence is available. Social rank was manipulated in studies of memory for cheaters, which provides an additional test of the hypothesis that processing information about cheaters is affected by social rank. In their pioneering study, Mealey et al. (1996) examined old-new face recognition for faces of cheaters, neutral, and trustworthy persons. They were primarily interested in testing the hypothesis that memory for cheaters is enhanced over memory for other types of faces, but they also included a manipulation of social rank by pairing the faces with high-status professions (e.g., a bishop) or low-status professions (e.g., a cashier). Interestingly, their initial hypothesis was that faces of high-ranking cheaters

should be attended, encoded, and recognized with a higher probability than the faces of low-ranking cheaters. Their reasoning was that the behavior of more powerful individuals is less constrained by situational factors, which means that the cheating of those individuals can be more readily attributed to internal character flaws. One may add that the cheating of a high-ranking individual (e.g., of an influential politician) may have more devastating consequences than the cheating of a low-ranking individual, simply because high-ranking individuals are more influential, and their decisions may be more likely to affect a larger number of people to a greater extent than those of low-ranking individuals.

Inconsistent with this *a priori* hypothesis, Mealey et al. (1996) found that the interaction was in the opposite direction of what was predicted. Furthermore, the results are less compelling than often claimed. Only the recognition of individuals with a low social rank was modulated by whether the face was paired with cheating, neutral, or trustworthy behavior. Even though this effect is often interpreted as evidence for (far) better memory for faces of cheaters (Cummins 1998), the difference between the cheater condition and the neutral control condition was much smaller than the difference between the neutral control condition and the trustworthy condition. Post hoc tests were not reported, but it is possible to conclude from the descriptive pattern of results that the effect was mainly driven by a decreased recognition of trustworthy individuals with a low social rank rather than by an enhanced recognition of cheaters with a low social rank, relative to a low-status neutral control condition, which is hard to reconcile with a functional perspective on memory for social interaction partners. As a post hoc explanation for the absence of any effect of behavior on the recognition of individuals with a high social rank, Mealey et al. proposed that the high attractiveness of the high-ranking individuals may have caused participants to ignore their untrustworthy behaviors. This interpretation was seemingly supported by the fact that female participants showed a descriptive tendency toward a better recognition of trustworthy individuals with a high social rank,

but this finding cannot be meaningfully interpreted because the three-way interaction between social status, behavior, and participant gender was not significant. Even if this problem is ignored, it remains debatable whether women should ignore the untrustworthy behaviors of attractive mating partners entirely. More important in the present context is that the pattern of results reported by Mealey et al. has been cited as supporting evidence for the assumption of dominance theory (Cummins 1999) that the cheating of low-ranking individuals should be monitored more closely (Cummins 1998, 1999, 2005).

Given the unexpected nature of Mealey et al.'s (1996) findings, it seems problematic to base strong conclusions on this single study. Fortunately there are several attempts to reproduce Mealey et al.'s findings that provide a clearer picture. Barclay and Lalumière (2006) repeated the study in two experiments ($N = 179$ and $N = 49$) and found no effect of social status, no effect of behavior, and no interaction between these two variables on face recognition in either of the experiments. Similarly, Mehl and Buchner (2008) found no evidence of a recognition advantage for faces of cheaters, no effect of social status, and no interaction between these variables in two experiments ($N = 96$ and $N = 123$). In a third experiment ($N = 64$), they found a small effect of social status (the faces of high-ranking individuals were recognized somewhat better than the faces of low-ranking individuals), but the effect was descriptively small. The interaction between social status and behavior was not replicated once again. In light of these failed replications, the findings of Mealey et al. should not be regarded as convincing evidence in favor of dominance theory (Cummins 1999).

Buchner et al. (2009) have argued that the null findings summarized in the previous paragraph are not necessarily problematic for any theory about cheater detection because recognizing faces as familiar cannot help to avoid cheaters and therefore does not provide an evolutionary benefit when the source or context in which the face was encountered is forgotten. What is required instead is the ability to remember that a particular person was associated with a history of

cheating. Indeed, source memory for faces of cheaters – that is, the ability to remember that an individual's face belongs to a cheater – was found to be enhanced in comparison to source memory for trustworthy or irrelevant individuals (see Bell and Buchner 2012, for a review). Most relevant in the present context, the source memory advantage for cheaters was not affected by social rank: Source memory did not differ between high-ranking and low-ranking individuals at all. This finding provides compelling evidence that people are equally interested in the cheating of high-ranking and low-ranking individuals.

Conclusion

In essence, then, there is as yet no reliable evidence that reasoning about social norms or memory for cheaters is affected by social rank. One study (Cummins 1999) demonstrates that high-ranking individuals may be more vigilant against the cheating of low-ranking individuals, but this finding can be attributed to the fact that some social roles with leadership status imply the duty to enforce social norms on others, which may affect the behavior of participants assigned to those roles accordingly. Other studies (Fiddick and Cummins 2007; Fiddick et al. 2013) show that high-ranking individuals are more tolerant of the cheating of low-status persons, but this finding may have to be attributed to the specific relationship between a boss and his or her employee rather than to status differences per se (Fiddick and Cummins 2007). Other lines of research either show a highly inconsistent pattern (Fiddick and Cummins 2001) or have demonstrated that social rank has no effects at all (Barclay and Lalumière 2006; Buchner et al. 2009; Mehl and Buchner 2008). In sum, the results seem to suggest that the relationship between social rank and social reasoning is determined by the specific situation. Although the idea that people may be biologically prepared to deal with social dominance hierarchies sounds quite plausible, the available evidence suggests that this does not necessarily include specialized modules for reasoning about norm violations or

memory for cheaters. More research is necessary to gain a deeper understanding of the conditions under which the processing of exchange-related information is affected by social hierarchies.

Social Relations Theory (Fiske)

Zachary Willockx

Oakland University, Rochester, MI, USA

Synonyms

[Moral relationships](#); [Social structure](#)

Definition

A set of psychological models centering on social relationships.

Introduction

Much of social psychology examines human behavior as a product between the individual and the situation. This focus led to many distinct findings that some argue were poorly explained (see Fiske 1991). With no overarching theory to guide them, most studies were presented as individual findings, unconnected to other findings within social psychology. To remedy this, some social psychologists had proposed unified theories of social psychology. However, these theories assumed humans thought of other humans as if they were inanimate objects (Fiske 1991). To counter this, Fiske (1992) proposed a unified theory of social relations that could help explain many findings in social psychology. This theory presented four psychological models that focus on human social relations: communal sharing, authority ranking, equality matching, and market pricing.

Communal Sharing

Communal sharing relationships are created through the notion that everyone within a communal group are both equal to one another and bound to one another. In this model, members of a group treat each other relatively the same, and

relationships are focused on disregarding individual differences and embracing commonalities. A key feature of these relationships is the belief that some immutable substance is shared across the group (e.g., genes, spirit). This psychological model is most often found in kinship ties, but can be seen in many ethnic identities or other such tightly bound groups. A common example of communal sharing groups is found in hunting and gathering societies. In these societies the whole group shares the meat of animals killed, and tools are shared freely (Marshall 1961). An important aspect of this form of sharing is the communality of land; land cannot be bought or sold, and it frequently becomes closely associated with the group living on it (Elias 1956).

One key feature of communal sharing relationships is the division of those outside the communal group into different classes that can be compared. For example, non-kin may be divided as neighbors and non-neighbors. Neighbors may receive the same resource support as kin, whereas non-neighbors may not, but both groups are socially equivalent for the purposes of alliance building in times of conflict. This type of psychological model may be especially useful when needing to keep track of large numbers of others while maintaining an in-group bias.

Authority Ranking

Authority ranking relationships function by building asymmetrical relationships among others who are ordered in a linear and hierarchical structure. These relationships are defined by a salience of one's rank compared to those around them, namely, determining if others are higher or lower than oneself in the status hierarchy. Individuals with a higher rank tend to have higher prestige, privileges, and deference by those below, whereas those with a lower rank are generally entitled to protection by those above them. These differences can be seen in the explicit rhetoric used, and the space granted, to those with more status in Western societies; those higher in rank are referred to as "higher-ups" and to be knocked down is to be "belittled." Moreover, those with more power are

given offices on higher floors with more space, whereas being sent to work in a basement is an insult.

A key feature of these relationships is the linearity of the ordering; no two individual can have the same status, and status is seen as unidimensional. For example, if person A is said to have a status equal to or greater than person B and if person B also has status equal to or greater than person A, then person A and B must be the same person. This means there are no branches or loops in an authority ranking relationship; the order among a group using such a relationship must be perfectly linear. Thus, this theory states that when individuals think in a linearly structured relationship model, they treat higher ranks as better.

Equality Matching

Equality matching relationships are based on an egalitarian form of justice, where retribution equals the harm. The main concern for those in such a relationship is balance. This is similar to a communal sharing relationship, except the focus of such sharing is on reciprocity, not care. In other words, everyone shares as a consequence of the threat of retribution, not because they feel any special affinity for those they are sharing with. As there are no assurances that everyone will pull their full weight in these relationships, individuals spend more time ensuring a one-for-one relationship to try and catch potential cheaters/freeloaders as soon as possible. Some common forms of these relationships are car pools or baby-sitting cooperatives. If a deficit is noticed, the cheater may be expected to give more to equalize the balance. For example, if an individual claims to be injured and cannot work a communal field one day, they may be expected to work the field alone the next time the group takes a day off.

Two key features of these relationships are linearity of debt and irrelevance of order. The first feature refers to the way humans conceptualize equality, stating that a debt of two carpool trips is exactly one step worse than a debt of one carpool trip, which is exactly one step worse than no debt. This second feature of these

relationships, the irrelevance of order, states that the way a debt is gained is irrelevant to the requirements for paying off the debt. For example, failing to carpool twice, carpooling once, and then failing to do so three more times are no worse than failing to do so three times, carpooling once, and then failing to do so two more times. Either way you have failed to balance your debt four times.

Market Pricing

Market pricing relationships focus on proportionality in social relationships. This means that everything in consideration is condensed into a single value that allows for comparisons to others. There are many such metrics, such as social value or money. As in the equality matching model, these ratios are linear, but unlike in equality matching model, the values can be compared to non-like concepts. For example, if two individuals in the carpool group were also in a group that watched each other's children, one failure to carpool would have no direct relationship to one failure to care for children. However, in market pricing relationships, you can compare these things. For example, if you owe someone a horse but all you own are dogs, each dog has a value so there will be some number of dogs whose collective value is worth more than the value of the horse you owe.

Conclusion

Fiske (1992) presented one of the most comprehensive and, for its time, novel approaches to a unified theory of social psychology seen in academia. By supporting his research with numerous cultural studies using a varied methodology, Fiske demonstrated that his theory not only accounted for many of the findings within social psychology, but that his theory could also be applied in cross-cultural research. In particular, he demonstrated a theory that was flexible enough to account for massive cultural differences without violating previous findings within social psychology.

Definition

Social reputation refers to the global impression that individuals within a community hold regarding a particular target individual. From an evolutionary perspective, we can think of one's social reputation as largely existing on a continuum with selfish on one end and other-oriented on the other.

Introduction

From an evolutionary perspective, the issue of reputation is initially something of a conundrum. That is, evolution generally selects for attributes of organisms that primarily and ultimately facilitate one's own probability of survival and/or reproduction (Dawkins 1976). To understand the relevance of one's social reputation from an evolutionary perspective, we need an understanding of the fact that humans evolved in contexts in which we interacted with the same other individuals repeatedly over long periods of time in small-scale societal conditions (Dunbar 1992). Further, a hallmark of being human pertains to the fact that these social conditions included a mixture of kin and nonkin. In such circumstances, reciprocal altruism (see Trivers 1971), or helping others with an implicit expectation of help back at a future point, can evolve to be a very powerful force in shaping social psychological phenomena.

In fact, reciprocal altruism ends up being a foundational aspect of what it means to be human, and this concept can help us understand a broad suite of cognitive and emotional processes in humans (see Geher 2014). For instance, we can understand guilt in terms of the fact that this emotion emerges when people fail to reciprocate altruistic acts within one's social circle. Similarly, apologetic behavior can be understood as having the function of staying connected with others after some sort of transgression. From this perspective, we can see how cultivating a reputation as a pro-social individual (i.e., an altruist) can ultimately have benefits that flow back to oneself within the context of his or her social circle. On the other hand, having a reputation as someone who is selfish and not trustworthy could have very damaging consequences for oneself.

The Social Ecology of the Environment of Evolutionary Adaptedness

Prior to the advent of agriculture, our ancestors lived in small, nomadic societies in numbers rarely exceeding 150 (Dunbar 1992). And in these small groups of individuals whom you

would spend your whole life interacting with, about half were kin (i.e., genetically related individuals) and half were nonkin whom one interacted with regularly. An implication of this feature of the ancestral human social ecology is that human psychological processes were shaped to deal with about 150 total individuals, a number now referred to as *Dunbar's number*.

The importance and relevance of Dunbar's number is that our minds evolved for small-scale living and interactions. Further, because of our evolved affinity toward small-scale social groups, things like social reputation weigh heavily on our livelihood.

Reciprocal Altruism

In a social world in which an individual is surrounded by the same conspecifics (i.e., members of the same species) repeatedly over time, it is possible that reciprocal altruism could evolve. This is because that in such a context, helping others with an expectation of help in return is possible. In his classic treatise on reciprocal altruism, Trivers (1971) discusses three specific preconditions that must exist in a species for reciprocal altruism to be mathematically possible (as it would have to ultimately pay off in survival and/or reproductive benefits for oneself given how natural selection operates). These three conditions are as follows:

1. The social ecology of the species must be such that individuals live in small groups comprised of the same individuals.
2. The lifespan of the species must be relatively long (so that altruistic behavior has a chance of being paid back).
3. The members of the species must be able to recognize specific conspecifics as individuals (so that an individual is able to differentially reciprocate based on who is who).

Humans fit these criteria to a tee (see Trivers 1985). So it is not surprising that reciprocal altruism is a foundational feature of the human social world.

In a world in which reciprocal altruism is ubiquitous, you have to watch yourself. If you never help anyone, then you might be ostracized and shunned. Even hated. If you help anyone at any point with zero discrimination as to who has helped you in the past, you risk being seen as someone who others might take advantage of.

In their classic work on the cognitive psychology of cheater detection, Cosmides and Tooby (1992) provided strong evidence demonstrating that human logic-based reasoning is enhanced when we are primed to think about a scenario in which someone might be trying to cheat others in a social context. In other words, when we are primed to think about if someone is failing to reciprocate altruism, our minds seem particularly astute. This general finding fits strongly with the idea that reciprocal altruism is a foundational part of the human social world. Our evolved psychology is filled with adaptations that were shaped by the fact of reciprocal altruism.

The Emergence of Social Reputation

Cultivating a reputation as a trustworthy altruist within one's community has both potential long- and short-term benefits aiding one's capacity for survival and reproductive success. In fact, pro-social, other-oriented personality traits (e.g., empathy, kindness, high agreeableness) are highly attractive and sought-after in potential mates (see Buss 2003). Nesse (2007) argues that the unique, and sometimes extreme, altruistic tendencies of humans evolved due to mating competition and is possibly a result of runaway social selection processes. This *competitive altruism* has been found to be a successful courtship display used to attract others (Barclay 2010), specifically when these signals are socially conspicuous, serving to bolster one's social reputation.

While cultivating a reputation as an altruist is one clear social strategy in humans, there are clearly a plurality of social strategies that exist in our species. For instance, one may take another avenue for evolutionary success and instead choose to maintain his or her social reputation as a dark, confident, powerful, and fear-inducing individual. Such a dark strategy may be successful in certain

contexts. However, when it comes to human evolved social psychology, any behavioral strategy comes with a variety of costs and benefits.

One empirical study supporting the competitive aspects and direct effects that altruistic behavior has on one's social reputation found that participants chose costlier signals and helped more, to essentially "show off," when the altruistic behavior was public, rather than anonymous (Bereczkei et al. 2010). Public displays of altruism, even if costly, appear to have an overall payoff in terms of social recognition, prestige, and popularity. In other words, altruistic behavior may partly be about cultivating a positive social reputation.

Conclusion

Under ancestral conditions, humans evolved in small-scale societies, surrounded by the same others for the lion's share of their lives (Dunbar 1992). Related to this kind of social ecology, reciprocal altruism evolved as a basic aspect of how humans interact with one another. In such a social world, there are clear benefits to oneself that follow from helping others – especially in publicly observable contexts (see Barclay 2010).

While taking a selfish approach to life as a human may have various immediate kinds of pay-offs, being tagged as selfish in terms of one's social reputation within the group can actually be quite deleterious to one's life. Across one's entire social life, social reputation matters. And the evolutionary perspective helps us understand why.

Social Roles

Janine Bosak
Dublin City University, Dublin, Ireland

Synonyms

Role; Roles

Definition

A socially defined pattern of behavior that is expected of a person who occupies a certain social position or belongs to a particular social category.

Introduction

Social roles are a socially defined pattern of behavior that is expected of persons who occupy

a certain social position or belong to a particular social category. The construct of social roles is central to the social sciences, and it came into general use during the 1920s and 1930s by analogy to the theatre. Social life occurs as performances by social actors, who are constrained by the scripts of their roles; the same actor can perform very different roles in different plays, and different actors can perform the same role quite similarly (Biddle 1986).

Types of Roles and Role Theory

At an individual level, roles function as schemas, that is, mental concepts that inform a person about how to behave in a particular role or situation. In addition, these role schemas are important structures at societal level as they tend to be consensual, (i.e., shared by members of society), and all persons in a society can be expected to support these shared behavioral expectations. Roles are therefore aspects of social structure that can be regarded as “persisting and bounded patterns of behavior and interaction among people or positions” (House 1995, p. 390). Different types of roles can be distinguished from each other (see Turner 2001). *Basic* roles, which are based on membership in general social categories (e.g., gender, age, ethnicity), have great generality because they affect all portions of an individual’s daily life. In contrast, *position* or *status* roles, which are based on, for example, occupations (e.g., firefighter, nurse) and family relationships (e.g., father, daughter), are primarily important for one’s behavior in particular settings (e.g., organizational work-context) or in a particular group. *Functional group* roles, like “mediator,” “counselor,” and “devil’s advocate,” develop informally as individuals adopt situational identities during social interaction in a group setting. Finally, *value* roles, such as “saint,” “hero,” and “villain,” emerge in the context of very positively or negatively valued behavior. It is also important to note that social roles can be either ascribed (e.g., gender, age) or achieved (e.g., parent, doctor).

Role theory is concerned “with the organization of social behavior at both the individual and collective levels” (Turner 2002, p. 233). Individual behavior in social contexts, tasks, and responsibilities in work groups and organizations,

as well as participation in society are organized into social roles. The role construct implies that individuals, who occupy the same social position within a social structure (e.g., organization, family), or who belong to the same general societal category (e.g., as men, as African Americans), are subject to the same situational constraints that help maintain their characteristic patterns of behavior. These constraints stem from the mental schemas for roles, for example, schemas for the daughter role, the doctor role, or the hero role, which people in their society share. As these schemas entail shared norms for appropriate conduct in these roles, “all persons in the system can be counted on to support those norms with sanctions” (Biddle 1986, p. 76). Role theory thus contributes to our understanding of the relationships among the micro-, meso-, and macrolevels of society.

Approaches to role theory can be broadly categorized via their most important distinguishing characteristic; they are either *structural* or *interactional*. Structural theories, building on Linton (1936), focus on the collective level and view roles as a set of expected behaviors, which are linked to positions in organizations and statuses in society. Individuals play their assigned parts in scripts written by culture with minimal improvisation. However, a somewhat more dynamic approach to structural theory put forward by R. Merton (1957) grants role incumbents (e.g., nurses) the option to act out different roles in response to the varied expectations of different people of importance (e.g., doctors, patients, family members of patients, fellow nurses). These different roles which emerge from varied expectations toward the role occupant are labelled a *role-set*. In contrast, interactional theories, building on G. H. Mead, shift the focus on social stability to social change, social structures to social processes, and on conformity to role-making (Turner 1962). Scripts only broadly determine the behaviors of the actors; during performances, the role incumbent improvises and develops and changes the scripts in a way that combines elements of creativity with conformity. Human agency and creativity in shaping social structures are seen as critical to social life as are

social constraint and conformity. While the classification into structural or interactional approaches is the most critical one, Biddle (1986) distinguishes three additional subsets of role theories including functional role theory, oriented to analyses of stability in social systems; organizational role theory, which focuses on role conflict in formal organizations; and cognitive role theory, which studies role expectation-behavior relations.

Multiple Roles and Psychological Adjustment

Basic roles, like those attached to gender and age identities, coexist with specific roles, like family and occupational roles, and are relevant to a wide variety of situations, including social interactions that are also structured by these specific roles. In the workplace, for example, a nurse or firefighter holds a particular role defined by occupation but is, at the same time, a man or woman and, therefore, also acts in accordance with his or her gender role, i.e., shared expectations that apply to individuals based on their socially identified sex. Social role theory (Eagly et al. 2000) posits that in the presence of typically very constraining role information, gender roles become less influential determinants of a person's behavior. More generally, research suggests that people combine or average the expectations linked to specific roles and more basic roles, like gender roles. Experimental evidence has further shown that men's and women's occupancy of the same role reduced or even eliminated gender-stereotypical trait judgments (Bosak et al. 2008, 2012). Eagly et al. (2000) conclude that specific social roles (e.g., occupational roles) mainly influence how the tasks required by the role are accomplished by individuals, regardless of their basic roles. In contrast, basic roles (e.g., one's gender or sexual orientation) might “spill over” to impact the discretionary behaviors that are not required by the more specific social roles.

The coexistence of multiple social roles is also critical to the psychology of adjustment. A key concept is role conflict, which can be defined as

“the concurrent appearance of two or more incompatible expectations for the behavior of a person” (Biddle 1986, p. 82). With *intrarole* conflict, the role incumbent must reconcile incompatible expectations and demands associated with the role. For example, an employee might experience intrarole conflict when being asked to complete a task for each of his or her supervisors at the same time. With *interrole* conflict, the role incumbent must manage contradictory expectations associated with different roles. For example, the interface between work and family demands can be a significant cause of interrole conflict. Because of role conflict, role strain, i.e., the felt difficulty in fulfilling role obligations (Goode 1960), may emerge. In addition to role conflict, other structural conditions that might cause problems in social systems include, for example, role ambiguity, i.e., a condition in which the role lacks specificity or complete information to guide behavior, and role overload, i.e., a condition in which a person faces too many expectations. In general, research suggests that, in work settings, these demands are associated with stress, burnout, and higher intention to quit. For example, a recent study conducted in a Canadian hospital found that job demands, (i.e., role conflict, role overload), were positively associated with burnout among hospital staff, (i.e., emotional exhaustion and depersonalization), and that staff perceptions of human resources practices (including empowerment, information-sharing, training, and non-monetary recognition practices) reduced the perceived demands and, in return, burnout (Kilroy et al. 2016).

The conflict perspective was challenged by Sieber (1974) who advanced the idea of *role accumulation* according to which the advantages of pursuing multiple roles might accumulate more substantially than the disadvantages, to the incumbent's benefit. According to the role enhancement perspective, a larger number of roles will increase an individual's resources, social connections, power, prestige, and emotional gratification (Marks 1977; Sieber 1974; Thoits 1983). This shift in focus from investigating the negative consequences of combining multiple roles (e.g., being both a parent and an employee) to its

positive consequences has been particularly prominent in research on the work/nonwork interface – as evidenced by Greenhaus and Powell (2006)'s model of work-family enrichment. These scholars defined work-family enrichment as “the extent to which experiences in one role improve the quality of life in the other role” (p. 73) and propose that enrichment is bidirectional.

Conclusion

Social roles can be understood as a socially defined pattern of behavior enacted by a person in a particular social position or belonging to a particular social category. Different roles (e.g., basic roles, position roles) can be distinguished from each other and they combine, in the form of multiple roles, to influence people's behavior. The coexistence of multiple social roles has important implications for individual's psychological adjustment and well-being, although the two competing perspectives – i.e., role strain perspective versus role enhancement perspective – differ in their propositions of and explanations for the effects of multiple roles on well-being.

Definition

Social skills form a set of behaviors emitted in social interactions, which can contribute positively to relationships between peers and to the development of a relationship considered to be satisfactory according to a particular context.

Introduction

Social interaction is recognized as extremely important for the survival of the human species. Although competition was fundamental to evolution, cooperation was also significant in terms of building society (Yamamoto et al. 2018).

Main Text

The expression of feelings, attitudes, desires, opinions, or rights of a given person, in a manner that is appropriate to the situation in which they are, is an important factor for achieving social competence (Caballo 2006). It also involves respect for these behaviors when expressed by another person in order to reach a resolution of an immediate problem or to prevent future adversities. In addition, there are behaviors that permeate everyday circumstances in different areas of a subject's life, including, according to Del Prette

and Del Prette (2001), communication skills, such as starting, holding, and ending a conversation; civility (how to present oneself, greet someone, thank someone, etc.); exercising rights and citizenship, such as expressing opinions, agreeing, disagreeing, apologizing, admitting failures, interacting with authorities, ending relationships, expressing dislike, etc.; and work, such as speaking in public, solving problems, making decisions, mediating conflicts, etc.

Childhood is a crucial period for the elaboration of social skills, because it is the phase in which children are invited to develop a satisfactory repertoire for the construction of healthy bonds (Schneider et al. 2016). Parental educational practices have a powerful influence on the development of children's social skills, and they extend the skills they learn to other social environments. An experiment conducted by Warneken and Tomasello (2006) found that children as young as 18 months of age were able to choose behaviors to help a stranger rather than help themselves. This choice can be understood both from the nonverbal behaviors learned early on through parental practices and from gene predisposition to prosocial actions (Penner et al. 2005; Del Prette et al. 2013).

Although they can contribute, the genes related to prosocial behaviors are not enough for the development of good social skills. Oxytocin, a hormone secreted by the hypothalamus and considered the biological substrate of empathy, seems to positively influence prosocial behaviors such as cooperation, generosity, and reciprocity (Barraza et al. 2011; Thompson et al. 2013). The behavior of helping a stranger who is suffering can be explained by the neural empathy mechanism that favors the observer to create a representation of the emotional experience of others, increasing the possibility of helping (Preston and De Waal 2002).

Just as there are benefits derived from good SK, failures in the development of this area can lead to several and significant losses in a person's life. Non-skillful social behavior may make it difficult to create bonds and, consequently, to form a support network. From this, Del Prette et al. (2013) put social isolation as a risk factor

for early death. In addition, the same authors report that individuals with SK deficits may be considered more vulnerable to psychiatric disorders in general.

Conclusion

Humans are essentially social beings, and, in this sense, the ability to maintain themselves in social interactions seems to have a protective even now. The studies presented have demonstrated the importance of social skills, as well as the presence of biological mechanisms in prosocial behaviors.

Definition

Social status: a person's standing within the hierarchy of a community or society; economic resources: the ability to provide food directly through foraging or indirectly through money.

Introduction

Only 3–5 % of mammalian species have long-term pair bonds between males and females and paternal care (Clutton-Brock 1991). Among great apes, the species most closely related to our own, in no species do fathers provide food for their offspring (Gray and Anderson 2010). Pair-bonding seems to have evolved in humans in part to facilitate paternal provisioning (Quinlan and Quinlan 2007). Forager men provide an average of 64 % of food, and in the USA married fathers provide more money for their family than mothers in about 75 % of households (Wang et al. 2013). This suggests that women have an

evolved preference for men offering resources, particularly when choosing long-term partners.

Preference for Social Status

Women display a preference for high social status in potential long-term mates across cultures (Buss 1989). Von Rueden et al. (2010) revealed that in a small-scale forager-horticulturalist society more similar to the societies in which humans evolved than industrialized societies, high-status men had more children within their marriages, and those children were less likely to die before reaching adulthood either because of genetic quality, better access to resources or both. This suggests that high status positively affects men's wives' reproductive success. Furthermore, a study of 186 pre-industrial societies demonstrated that women value social status in men because of the benefits it brings to their mutual children: high-status men have more wives and are better able to feed their children (Betzig 1986).

Women in industrialized societies also prefer high-status men as long-term mates. Buss' (1989) study of 37 industrialized nations across the globe found that women value ambition-industriousness more than men in 78 % of the countries sampled, and in only one country did men value the same trait more than women. Recent studies have shown that social status is a necessity for women selecting a long-term mate: it is highly valued when scarce, but diminishes in value once sufficient levels of it are obtained (Li, Valentine, & Patel, 2011). A series of speed-dating studies demonstrated that this preference is not merely theoretical; women prioritize social status when choosing long-term mates in a live-interactive setting (Li et al. 2013).

Preference for Economic Resources

If women select men with high social status because of the resources that such men can provide women and their future children, then a more direct preference for men with resources should

also be evident. Indeed, it is. Among the Hadza foragers, good foraging ability was the most common trait that women listed as being important in a spouse (Marlowe 2004). Furthermore, in the 37-nation study discussed above, women value "good financial prospect" more than men in 36 of the 37 cultures sampled. In a nationally representative US sample, these results were conceptually replicated: women were found to be more willing to marry someone who earns more than them and less willing to marry someone who earns less than them compared to men (Sprecher et al. 1994). Similarly, women value earning capacity more than men at every level of involvement, and a higher earning capacity is required at each stage of commitment (dating, sexual relations, steady dating, and marriage; Kenrick et al. 1990). Just as we saw with social status, there is also real-world evidence that women prefer men with more resources as long-term mates. Income significantly predicts how many replies men receive from personal ads (Baize and Schroeder 1995).

Conclusion

The survival of the fittest has favored women who select mates who give them the most benefits with the fewest costs. One benefit men can bestow upon women is resources. Women prefer men who can provide resources and men who have high status, a signal of the ability to provide resources as long-term mates. This preference has been found in both preindustrial and postindustrial countries and has been demonstrated in studies with high ecological validity. However, that does not mean that this preference is insensitive to context. Women's personal resources and women's mate value can impact the extent to which social status and resources are prioritized (Zentner, this volume; Edlund and Beck, this volume).

Social Tool

Ivo Jacobs and Mathias Osvath
Lund University, Lund, Sweden

Definition

A tool directed toward another animal (social target) or the use of another animal as a tool (social means).

Introduction

Tool use in nonhuman animals takes many forms. Social tool use consists of two different categories. Social-target tool use involves an animal using a tool toward or for the purpose of another animal. For instance, a male gila woodpecker often fed his offspring with honey, but this proved difficult when the honey was thinned down. He then removed pieces of bark and dipped them in the honey, which allowed him to transport it to his offspring. Thus, the bark was a tool that functioned to transport a liquid to a social target. The second category is social-means tool use: using another animal as a tool. For example, African elephant bulls have been observed to pick up and throw young bulls at fences, which broke and consequently enabled the bulls to pass. The young bulls were used as throwing tools. Some cases involve both social-target and social-means tool use, such as when a chimpanzee hits another

chimpanzee with a dead colobus monkey (examples from Shumaker et al. 2011).

Based on Shumaker et al.'s (2011) general definition of tool use, social-target tool use is the external employment of an unattached or manipulable attached environmental object to alter more efficiently the form, position, or condition of another animal (not the user itself), when the user holds and directly manipulates the tool during or prior to use and is responsible for the proper and effective orientation of the tool. Social-means tool use is the external employment of another manipulable animal (the tool) to alter more efficiently the form, position, or condition of another object, another organism, or the user itself, when the user holds and directly manipulates the tool during or prior to use and is responsible for the proper and effective orientation of the tool.

The majority of tool-use modes can be social-target tools and social-means tools. Some modes even require a social target, such as using a tool to stab, beat or entice others. Tools can also be used to create or augment a display, which clearly has a social component. However, our definition excludes certain behaviors that are sometimes regarded as social tool use (e.g., Johnson 2010; Völter et al. 2015) because the tool is not physically manipulated by the user. Examples of excluded behaviors are social learning of tool use, material culture, recruitment, communication, deception, tool sharing, and cooperation. Nonetheless, this distinction is not absolute and is only based on their typical aspects. For instance, communication may involve social tool use when an object is used to create or augment a social display.

Social-Target Tool Use

One of the most common types of social-target tool use is agonistic dropping or throwing. Some bird species and most primates appear to do this, with the exception of prosimians (Hunt et al. 2013; Shumaker et al. 2011). It is sometimes argued that only aimed throwing and dropping should be considered tool use, but this is often difficult to determine. Moreover, throwing and dropping may have the same function whether

aimed or not; they can effectively intimidate, threaten, or displace others (Osvath and Karvonen 2012). Some unaimed dropping and throwing appears to be stereotyped displacement, or originates from it, which could then have developed into aimed social-target tool use (Hunt et al. 2013).

Social-target throwing may also arise through complex cognitive abilities. Some chimpanzees pile feces or wet chow to later throw at visitors (Hopkins et al. 2012). A zoo-housed male frequently planned for future stone throwing by collecting stones and caching them while he was calm and no visitors were present. Later during the day he would retrieve and throw these stones at visitors during dominance displays. He also innovated this behavior, most notably through tactical deception. For example, he chipped off concrete projectiles but desisted throwing them because the visitors were told to back away. When the group returned 3 h later, the chimpanzee calmly picked up an apple from the surrounding moat while holding two projectiles (see Fig. 1). He suddenly threw one when within range of the group. The nonchalant behavior preceding the throw follows the deceptive strategy of creating a neutral image. Deception was also evident from his frequent concealing of projectiles when no visitors were present (Osvath and Karvonen 2012). Such inhibition of a prepotent social response that will be more effective in the future can be highly advantageous for animals living in groups with a hierarchical structure (Parker and Gibson 1977).

Not all chimpanzees are habitual projectile throwers. Only 39 out of 91 chimpanzees threw consistently in one group. Those that did had greater cortical connectivity in areas of the brain that are associated with motor control and speech production in humans. These differences were mainly present in the brain hemisphere opposite to their preferred throwing hand, which was also the hand they mostly used in other tool tasks and gestural communication. This contralateral brain-limb association is likewise typical for humans. Chimpanzees that had learned to throw scored better on tests of communicative abilities than those that did not. There were no differences in performance on other tests of social and physical

Social Tool, Fig. 1 Deception by a male chimpanzee preparing for social-target tool use. He holds two projectiles in his left hand and calmly picks an apple from the moat. He then approaches the visitors and suddenly throws the projectiles toward them. Reproduced from Osvath M,

cognition. Both throwing and gestural communication serve to alter the behavior of others, although it is unclear whether one is the result of the other (Hopkins et al. 2012).

Social-Means Tool Use

Using another animal as a tool seems to be rarer than social-target tool use. In one case, a large troop of Japanese macaques was provided with food in a long transparent tube. They were conditioned to use stick tools, and some learned to throw stones to push the food out. Other macaques often waited at the far end of the tube so they could steal the food if a tool user threw a stone against it. The tube was wide enough for infants to enter, and two females pulled back theirs if they spontaneously crawled into the tube and collected the food. Another female used all four of her infants as social-means tools by actively pushing them into the tube and pulling them back once they retrieved the food. The advantages of this tool use are that the tool was always available, in contrast to sticks and stones that could be buried under snow, and that scroungers could not wait at the other end of the tube to steal the food (Tokida et al. 1994).

Orangutans can also use their offspring as social tools. In one experiment food was placed behind a barrier with holes too small for the hands

of adults. Each of three orangutan females frequently used their juvenile offspring as tools by moving them toward the barrier, pushing their hands through a hole, or pulling their arms once they grabbed the food. Similarly, when food was placed behind a small door opening, the mothers pushed the juveniles through, held on to their limbs, and pulled them back as soon as they retrieved the food. They then took the food from them. Similar results were found when the goal was a tool that could be used to retrieve inaccessible food, which shows that orangutans can use tools sequentially with the first tool being a social-means tool. In forced choice experiments, the juveniles preferred to take the food but were often coerced by their mothers to take a tool that they then used to retrieve preferred food. They were also sometimes moved through the narrow door opening if they could use a tool there to obtain food for themselves and their mothers (Völter et al. 2015). Orangutans also throw objects at dogs and even pull humans toward a goal so they can use them as ladders (Köhler 1993). These experiments show that orangutans can adjust their behavior flexibly by using others as social tools.

Social-Means-Target Tool Use

A triadic interaction is necessary when both social tool use types are combined. The user manipulates

another animal as a tool to affect a third animal in social-means-target tool use. However, it does not follow that all triadic interactions involve social tool use, as some researchers have claimed (e.g., Johnson 2010), when the user does not physically manipulate the tool. One type of triadic interaction that does involve social tool use is *agonistic buffering*, in which an animal uses another animal as a tool to discourage attacks from an aggressive target. Primates such as macaques, baboons, bonobos, and chimpanzees sometimes hold infants to inhibit potentially agonistic interactions. In some cases they instead used infants to get third parties to follow them or elicit affiliation from them (Johnson 2010; Parker and Gibson 1977; Shumaker et al. 2011).

A very different kind of social-means-target tool use is found in boxer crabs. They hold small stinging anemones in their claws and use them to catch food. They also use these anemones as protection against threats or as weapons in fights with other crabs. This behavior mostly encompasses twitching, waving, and extending the anemones. Contacting other crabs with anemones only rarely occurs. Fights are often ritualized in many animal species, which include the weapon use of boxer crabs that could inflict serious damage on contact (Karplus et al. 1998).

Conclusion

Social tool use can involve cognitive complexity that is traditionally only associated with nonsocial tool use. Although learning socially to use tools and the psychological manipulation of others are interesting behavioral categories, they should be seen as distinct from social tool use because the user exerts no direct physical control over the purported tool, which is instead regarded as a self-propelled agent. With our operational definition, social tool use can be investigated as being both a social and tool-related behavior, which offers unique avenues for future research.

Synonyms

Community principles; Cultural doctrines; Cultural elements; Ethics; Moral codes; Social customs; Social norms

Definition

Moral codes that characterize human societies; cultural elements that bring together a group of individuals and render humans as the only species to be separated qualitatively from animals on the basis of social order and community.

Introduction

Societies seek to establish congruence between social values associated with their activities and the norms of acceptable behavior in a larger social system. Values foster harmony within a human society and function as the foundation of organizational legitimacy. Absence or violation of cultural, common values leads to disparity that can threaten congruence and undermine unity within a society. As communication is a vital component in the realm of enculturation, language appeared to develop in parallel with human cultural values. Human species evolved over generations, and communication became more complex. Arbitrary cultural meanings are found to be assigned to rites of passage and initiations of individuals in communities, as well as animate and inanimate objects. Interpretively, this allows for a vivid evidence that early culture rituals were occurring,

enriching the notion of human civilization that was continuously on the rise.

Emergence of Identity Within Culture

In developing their sense of identity, people identify successively with values of influence over their well-being. The primary process involved in identity development is one of enculturation of cultural elements (Berry 1980). Enculturation references the agentic individual's process of identification with whatever cultural elements of influential others are accessible to the person (Weinreich 1983). In the main, the young child identifies with mother and father in the first instance but identifying only with limited aspects of them apprehended from the child's perspective (Mikhail 2011). Subsequently, the person as older child, adolescent, and then young adult successively identifies with members within their direct environment, and beyond with agents of the wider community, and part-identifies with their salient features according to increasing levels of comprehension (Erikson 1950, 1968). As a consequence, over a formative period, the child who becomes the adult migrant will have enculturated major aspects of heritage culture including some elements that are incompatible with others, since cultures are not entirely monolithic (Wrangham 1987). According to ISA, identity is a modification of earlier ones and emphasizes people's construal of their biographical past and their aspirations for the future. For human species, their biographical past scenarios can be located in their heritage locations and cultures (Boesch 2007), while their future aspirations entail considerations about their intended modes of engaging with their receiving communities (Weinreich 2003).

Embodiment of the Self in the Community

Rites of Passage

A rite of passage is a ceremony and marks the transition from one phase of life to another. It

plays a critical role in the evolution of human civilization as it defines the common values of a society (Tooby and Cosmides 2005). A rite of passage manages to conserve social order and the sense of community among the members of a group who come together to celebrate an occasion and practice traditions and customs on the foundation of shared social values (Yamamoto and Tanaka 2009). Rites of passage are characterized by the ordeals with which a youth is formally invested with adult status in a community. Intriguingly, these rituals and ceremonies allow adults to transition into new life roles along the path of adulthood, all the way into meaningful elderhood. When humans design rite of passage experiences, they work to assure that initiates come out of the experience with a new and empowering story that helps them take responsibility for the decisions that set the course of their future (Sober and Wilson 1998). Members of social group initiates create the story of who they are and the kind of life they wish to build based within the exploration of their own personal values (Haidt 2003). Initiates are encouraged to select the story that connects them to their community. Through this self-exploration, they emerge with a stronger sense of personal responsibility to all aspects of their lives, stretching all the way out to the larger world of which they are a part of (Carrithers et al. 1985). Consequently, both the community and the initiate benefit from a rite of passage. An intentional rite of passage experience provides the space for the community to transmit its core values and ethics and confer the role responsibilities appropriate to the initiate's stage of life (Frank 1988), hence, insuring cultural continuity and knitting together of the generations.

The Role of Honor Code

A fundamental aspect of culture is its embodiment of the societal processes of substantial groups of people who perceive themselves as belonging to a commonality of values and beliefs, moral imperatives and religious beliefs, dress and behavior, history, and modes of living, whereby one group is culturally distinctive from another (Henry 2008). From evolutionary

perspective, Honor Codes appear to maintain cohesive order within communities. The role of an Honor Code is to encompass a set of ideals in a society and govern accordingly a group of individuals that abide by moral rules. It is based on what constitutes honorable behavior among group members, and its use depends on the notion that individuals within the group can be trusted to act honorably (Locke 2014). In many cultures, an Honor Code exists parallelly to ethics that require proper compliance according to societal rules, by members who seek to be recognized for their individuality and be inviolably included in community. Punishments upon disregard of the Honor Code underline that values-driven individuals ought to be more successful within a society.

Development Levels for Compliance and Ethics

From evolutionary perspective, crucial components that characterize Honor Codes of human societies appear to be diachronic as they influence critically the man of today who seems to adhere to values that had always fostered healthy functions in communities since ancient times (Hagan and Hammerstein 2006). Modern society has adopted these values and incorporated them into organizational Honor Codes. Foundation level programs set the basis for establishing a healthy organizational culture and preventing, detecting, and resolving legal and regulatory compliance violations (Shafer-Landau 2012). The behavioral focus is on compliance and the business focus is on the organization. Transformation level programs support a shift from a compliance focus to a compliance and ethics focus. The behavioral focus is on compliance and ethics promoted by values-based leadership. The business focus is on the organization and primary stakeholders which might be customers, suppliers, investors, financiers, and communities in operating area. Sustainability level programs foster aspirational behavior and contribute to the organization's continued success. The behavioral focus for this level is on compliance, ethics and honor, collaboration, and meaning, all promoted by values based on

leadership. Hence, the business focus is on the organization, primary stakeholders and secondary stakeholders which might be special interest groups, media, government, competitors, consumer advocates, and global society (Henry 2008).

Conclusion

The continuous process of human enculturation is the foundation of the person's identification as well as the coexistence of mixed cultural elements within the person's identity. Ultimately, the goal is the creation of elemental identification that is characterized by common social values and is expressed within social boundaries and moral incentives. The values of shared ethics, Honor Codes, and rites of passage appear to be among some of the most crucial components to maintain social norms and community order intact in human communities. The purpose of social values is not to cultivate individuals who blindly appraise ideals of a rather unknown cultural history. The concept of culture is not only characterized by participation of the individual in community but also by the separation from the massive group in an attempt to acquire identity and authentically accustom by the values that define the broader society they live in. The goal is a new emerging self that can actively engage in rituals and celebrate ideals while she or he questions the nature of traditions and seeks to gain knowledge regarding the historical background that determines their identity.

Social Withdrawal in Childhood

Will E. Hipson¹ and Robert J. Coplan²

¹Department of Psychology, Carleton University, Ottawa, ON, Canada

²Carleton University, Ottawa, ON, Canada

Synonyms

Preference for solitude; Social avoidance; Social isolation

Definition

Process whereby children remove themselves from opportunities for social interaction and engage in solitary activities in the presence of peers.

Introduction

Interacting with others is an integral part of childhood. Making new friends, playing with a group of peers, and being liked and accepted by classmates all represent critical and formative experiences for children. For most children and adolescents, the considerable amount of time spent in the presence of peers is not only perceived as enjoyable and fulfilling but also serves to provide opportunities to learn and refine important social, emotional, cognitive, and linguistic skills. Notwithstanding, some children still choose to engage in solitary activities in lieu of social interaction with peers. Social withdrawal refers to the process of removing oneself from opportunities to interact with others (Rubin et al. 2009). The concept of social withdrawal extends beyond the broad notion of a physical separation from others and involves a complex combination of motivational, emotional, and cognitive factors. For example, for some children, social interaction may elicit powerful feelings of anxiety. In contrast, others may seek out

solitude for its own enjoyment. Regardless of the underlying reasons for not engaging with peers, social withdrawal is implicated in social maladjustment across childhood, and *excessive* social isolation may have severe consequences for children's social, emotional, and psychological well-being.

Defining Social Withdrawal

Social withdrawal is an umbrella term that encapsulates a range of behaviors and motivations associated with removing oneself from opportunities for social interaction (Rubin et al. 2009). This construct is meant to be distinct from the process of *active isolation*, whereby children are ostracized or excluded by peers (thus preventing them from engaging in social interactions) (Rubin and Mills 1988). However, these appear to be transactional processes that influence each other over time (Rubin et al. 1991). For example, individuals may respond to social ostracism by seeking out solitude (Ren et al. 2016). Likewise, socially withdrawn behaviors may elicit negative peer responses, including peer rejection and victimization (Coplan et al. 2015b).

Children may be motivated to withdraw from others for a variety of reasons, which can have specific implications for their social adjustment and well-being. For instance, some socially withdrawn children experience elevated fear, anxiety, and self-consciousness in social situations and may avoid social interaction to alleviate these negative emotions (Crozier 1995). Alternatively, other children engage in solitary activities, not out of social wariness, but because they find solitude intrinsically rewarding and enjoyable (Coplan and Weeks 2010). Notwithstanding these underlying motivations, there is reason to be concerned about social withdrawal in childhood. From an evolutionary perspective, social interaction is adaptive because it facilitates social bonding and individual happiness. Consequently, frequent social withdrawal in childhood is viewed as *maladaptive* because it may pose substantial risks for children's socio-emotional adjustment and well-being.

Social Withdrawal as Evolutionarily Maladaptive

A strong case has been made for considering childhood social withdrawal as evolutionarily maladaptive. In this section, we consider these arguments at both the level of the species (e.g., notions of natural and sexual selection) and the individual (e.g., concurrent and predictive implications for the child).

Survival and Reproduction

Humans are fundamentally social beings, capable of forming complex social hierarchies and intimate social bonds. This penchant for social interaction is considered to have been an essential ingredient for the survival and proliferation of our species (Campbell 1983). Cooperation promotes survival, resource exchange, and abundance and fuels the growth of large-scale communities (see Reeve, ► [Evolution of Cooperation](#)). Additionally, interpersonal communication fosters intimacy and trustworthiness (see Scalise Sugiyama, ► [Gossip and Grooming Hypothesis](#)). Failing to partake in social rituals may result in reduced social status in the community or outright ostracization.

Moreover, as evidenced among human and many nonhuman species (e.g., great apes), a disposition toward social dominance and assertiveness is favorable to siring offspring, thus increasing the prevalence of such traits in the population (see Moore, Starkey, & Benjamin, ► [Dominance in Humans](#)). Those lacking such traits would have diminished access to resources (e.g., food and protection) and fewer opportunities to mate due to decreased sexual competitiveness (particularly under stressful circumstances, e.g., Boyce et al. 1998). Taken together, evolutionary reasoning supports the view that sociability and assertiveness are assets for both an organism's survival and their ability to reproduce and pass on their genes.

Childhood Peer Interactions and Relationships

Social withdrawal is also viewed as maladaptive because of its potentially adverse impact on

children's interactions and relationships with peers. Children's early peer interactions lay the groundwork for the acquisition of social competencies, while the formation of peer relationships further strengthens social skills and facilitates optimal adjustment (Rubin et al. 2015). As such, children who consistently eschew opportunities to play with others in favor of solitary play may miss out on formative social experiences integral to the development of social skills (Rubin et al. 2009). This may contribute to further social isolation as these children may lack confidence in their abilities to engage with peers.

Moreover, socially withdrawn children tend to garner more negative reactions from peers. Social expectations and norms regarding the quantity (and quality) of peer interactions rise steadily from early childhood to adolescence (Rubin et al. 2015). By late childhood, peer interaction is clearly the norm. For example, Coplan et al. (2015b) observed children in grades 4–7 in the schoolyard over recess and lunch and reported that, on average, children interacted with a peer or peers more than 90% of the time. Thus, withdrawing from the peer group in this context is likely to be viewed as socially deviant. Societal expectations and norms regarding social interactions may help explain why withdrawal appears to be more problematic for boys compared to girls (Doey et al. 2014). Indeed, shy boys tend to garner more negative responses from peers and experience more peer exclusion and rejection (Gazelle and Ladd 2003; Spangler and Gazelle 2009). It is hypothesized that withdrawn behaviors violate typical gender norms ascribing assertiveness and dominance among boys, contributing to more negative reactions from peers (Doey et al. 2014).

It should not be surprising that socially withdrawn children are often isolated by peers (Spangler and Gazelle 2009). This can lead to a transactional process whereby peer rejection and exclusion exacerbate children's retreat into social withdrawal, which in turn serves to further promote negative peer experiences (Rubin et al. 1991). Moreover, when socially withdrawn children do form friendships, these relationships tend to be of lesser quality as compared to their more sociable counterparts (Pedersen et al. 2007; Rubin

et al. 2006). This also appears to hold true in the context of romantic relationships, with socially withdrawn adolescents having fewer and less intense romantic partnerships (Boisvert and Poulin 2016).

Peer difficulties among socially withdrawn children also extend beyond isolation and rejection to more overt victimization (Hanish and Guerra 2004). Victimizers may view socially withdrawn children as “easy targets” given that they are sometimes perceived to be physically “weak” and less likely to retaliate when confronted (Rubin et al. 2006). Additionally, deficiencies in social skills may expose these children to further mockery and ridicule, thus perpetuating a reciprocal relation between social withdrawal and peer rejection (Greco and Morris 2001).

Taken together, social withdrawal appears to have an adverse effect on how children interact with and are treated by their peers. Particularly in late childhood where peer play is especially prevalent (Coplan et al. 2015b), solitude is likely to be perceived as atypical. In addition, frequent bouts of solitary play may hinder the acquisition and refinement of social competencies necessary for forming relationships with peers.

Happiness, Health, and Individual Well-Being

A final reason that social withdrawal may be maladaptive is that, overall, time spent with others makes us happier and healthier than time spent in solitude (see Coplan et al. *in press-b*, for a recent review). For example, simply being alone is associated with elevated levels of the hormone cortisol, which is implicated in feelings of stress (Matias et al. 2011). Moreover, most people just do not like spending time in solitude. Indeed, in a series of recent experiments, Wilson et al. (2014) demonstrated that most university students opt to self-administer electric shocks instead of being left alone with their thoughts for 15 min. Further, frequent solitude is tied to feelings of loneliness (Hawkley and Cacioppo 2010). Loneliness arises from a perceived dissatisfaction with the quantity and/or quality of one’s social relations (Cacioppo et al. 2015). Socially withdrawn children may become increasingly lonely with age as they develop more sophisticated self-concepts based

on their relative social standing among peers (Lempinen et al. 2017; Qualter et al. 2015). Loneliness can also have long-term detrimental consequences for one’s physical and mental health. Indeed, loneliness is associated with heightened cardiovascular problems, substance abuse, and mortality, as well as depression and chronic stress (Hawkley and Cacioppo 2010).

In contrast, interacting with others is generally associated with positive moods (Vittengl and Holt 2000). Experimental evidence suggests that social situations are perceived as more satisfying and enjoyable compared to nonsocial situations (Epley and Schroeder 2014; Sandstrom and Dunn 2013). Furthermore, even dispositionally introverted individuals report substantial positive feelings following social interaction (Zelenski et al. 2013). Scholars have historically espoused the view that humans have an innate psychological *need* to interact with others (Baumeister and Leary 1995; Maslow 1943), and people report greater life satisfaction and meaningfulness when they regularly engage in social interaction and partake in social activities (Demir et al. 2011). Similarly, children who have frequent, positive interactions with family and peers report greater happiness and a more positive self-concept compared to children who have fewer social interactions (Holder and Coleman 2009). Thus, the potential negative effects of social withdrawal on happiness and well-being are twofold: (1) being alone is associated with momentary decreases in happiness, and (2) excessive solitude is linked with loneliness and appears to have severe consequences for health and well-being.

Can Certain Subtypes of Social Withdrawal Be Adaptive?

To this point, we have focused on the myriad of potential reasons why the broad construct of social withdrawal might be considered evolutionarily maladaptive in childhood. However, as we have noted, social withdrawal itself is a multifaceted phenomenon that is now widely considered as comprising varying emotional and motivational substrates (Coplan et al. 2015a). Simply

stated, there are several different *reasons* why children might withdraw from opportunities for social interaction, and these varying motivations can have substantially different implications for children's social adjustment and well-being. For example, some children may socially withdraw because they experience unpleasant feelings in unfamiliar social situations. Children who are *shy* experience fear and wariness toward social novelty, as well as self-consciousness in situations of perceived social evaluation (Coplan et al. 2004). Shy children are also thought to experience an *approach-avoidance conflict*, whereby their desire to engage in social interaction is simultaneously inhibited by fear and anxiety (Asendorpf 1990). Shy children often have difficulty integrating into peer groups and may, instead, engage in onlooking behaviors during instances of peer play (i.e., watching without joining in) (Coplan et al. 1994).

Shyness is a risk factor for social adjustment difficulties throughout childhood and adolescence (Rubin et al. 2009). In particular, shy children are more prone to *internalizing problems* (Karevold et al. 2012), which involve retreating from one's environment and engaging in inwardly focused behaviors (Achenbach and Edelbrock 1981). Overall, as compared to their more sociable counterparts, shy children are more likely to experience anxious and depressive symptomology, as well as feelings of loneliness and low self-worth. Indeed, extreme shyness in childhood is one of the best predictors of later social anxiety disorder (Clauss and Blackford 2012).

Shyness, as a trait, is relatively enduring within the population, with estimates suggesting that roughly 15% of children are born with a predisposition toward heightened wariness (i.e., behavioral inhibition; Kagan et al. 1988), which is a precursor for social withdrawal (Chronis-Tuscano et al. 2009). Evolutionarily speaking, socially withdrawn traits would not likely have evolved to exist in humans if they were completely detrimental. One often cited advantage of heightened wariness is its survival value. Among animals across a range of taxa, shy-like traits (i.e., greater reactivity to novel stimuli) promote behaviors that reduce the likelihood of predation (Verbeek et al.

1994). Organisms predisposed to flee from potentially threatening situations had a greater chance of avoiding predation and passing on these genes. As such, heightened sensitivity to novelty is suggested to have evolved as a survival strategy (LeDoux 2000).

To a certain extent, this is evident among infants and toddlers exhibiting stranger anxiety – a tendency to avoid unfamiliar others (Mangelsdorf et al. 1995). As another example, Colonnese et al. (2014) suggest that certain behavioral displays of shyness such as a *coy* smile (i.e., the combination of smiling, avoiding eye contact, and tilting the head) can serve an adaptive function by reducing social tensions in potentially stressful situations (e.g., encountering a stranger). However, avoiding threatening situations is not synonymous with avoiding social interaction, and it has been argued that social withdrawal emerged as a *by-product* of evolutionarily driven mechanisms for heightened threat detection (LeDoux 2000).

Notwithstanding, some children may also socially withdraw because of an intrinsic, non-fearful preference for solitude. This type of social withdrawal is referred to as *unsociability*, *social disinterest*, and/or *affinity for aloneness* and is believed to be a relatively benign form of social withdrawal (Asendorpf 1990; Coplan et al. 2004). Moreover, emerging evidence suggests that non-fearful solitude seeking may be adaptive for some aspects of individual well-being, particularly among adolescents and young adults (Goossens 2014).

Although direct empirical evidence remains sparse (Coplan et al. in press-b), it continues to be argued that spending time alone can also promote intellectual, creative, and spiritual growth while reducing stress and anxiety (Korpela and Staats 2014; Long et al. 2003). In childhood, occasional solitary play promotes regulatory and exploratory behaviors, as well as facilitating identity formation (Galanaki et al. 2015; Katz and Buchholz 1999). Preschool children who engage in more constructive forms of solitary play score higher on measures of creativity and divergent thinking (Lloyd and Howe 2003). Moreover, researchers speculate that the benefits associated

with solitude become more salient over time in concordance with developments in identity and peer relations (Larson 1997). In early childhood, stronger social pressures to engage in group play may undermine the potential benefits of solitude, but advantages of spending time alone may emerge among older children with increasing positive and sophisticated views of solitude.

Despite these assertions, it remains unclear as to whether the proposed benefits (or lack thereof) of solitude in childhood can be attributed to those with a *trait-level* affinity for solitude, compared to the actual state of being alone. Excessive social withdrawal in children, regardless of whether it is motivated by an affinity for solitude, still warrants concern as it poses significant risks for children's social adjustment and well-being. Children who perpetually choose solitary play in place of peer interaction may fall behind in their development of social skills compared to their more sociable counterparts (Rubin et al. 2015).

Future Directions: Considering Context

Until now, this summary has largely focused on social withdrawal within the broader context of adaptive versus maladaptive outcomes in childhood and how these may vary as a function of children's social motivations. However, environmental and social contexts also play integral roles in defining attitudes toward socially withdrawn behaviors, which ultimately impact outcomes associated with social withdrawal. This final section addresses (1) the role of culture in children's social withdrawal and (2) how computer-mediated communication (e.g., texting, social networking, etc.) is actively changing the meaning of solitude and its implications for socially withdrawn children.

Culture

Research on social withdrawal and its concomitants was traditionally limited to predominately affluent Western populations. However, there is burgeoning interest in the meaning and socio-emotional impact of childhood social withdrawal across cultures. Culture plays an important role in

shaping attitudes and beliefs about social behaviors (Chen and French 2008). As such, certain cultures may view socially withdrawn behaviors in children more or less positively, which in turn can influence its implications for socio-emotional adjustment and well-being.

For example, traditional Chinese society values group harmony and cohesion over assertiveness and independence, which helps to explain why Chinese parents, teachers, and peers have historically been more accepting of children's shyness (Chen et al. 1995; Oyserman et al. 2002). Consequently, shyness was formerly associated with greater academic success and led to comparatively fewer instances of peer rejection (Chen et al. 1995). However, ongoing shifts in China's economic and political landscape (e.g., amplified pressures to compete in a Western dominated economy) have placed heightened value on assertiveness, particularly in urban Chinese societies (Chen et al. 2005). Consistent with Western cultures, shyness in Chinese children is currently linked with peer difficulties and internalizing problems (e.g., Coplan et al. 2017). However, in contrast to Western society, unsociability (i.e., a non-fearful preference for solitude) is also associated with social adjustment issues among Chinese children (Liu et al. 2015). Indeed, despite an increased value of assertiveness, interdependence and group affiliation remain core values in Chinese culture, such that a preference for solitude may be discouraged for deviating from entrenched societal norms (Chen and French 2008). Thus, cultural context exerts considerable influence on our attitudes and beliefs about social withdrawal, which in turn effects how family and peers respond to socially withdrawn children.

Computer-Mediated Communication

Advances in communication technology also have considerable import on our understanding of social withdrawal and its developmental significance. Among older children and adolescents (and increasingly among younger children), conversing and networking with peers via online social media platforms and text messaging are pervasive in developed countries and proliferating in developing countries. A recent poll of

adolescents in the USA indicated that roughly 90% of adolescents have access to a mobile phone and almost 25% report using these devices constantly (Lenhart 2015). It thus appears typical for older children and adolescents to be *physically* isolated yet actively communicating with peers across any number of media platforms. This has prompted a conceptual reconfiguration of the definition of social withdrawal to expand beyond face-to-face communication.

The impact of social media and online communication among socially withdrawn children remains largely unexplored. Some have argued that online communication may exacerbate social withdrawal and impede the development of social skills that are otherwise acquired via in-person interaction (Hamburger and Ben-Artzi 2000; Kraut et al. 1998). According to this perspective, socially withdrawn children may resort to online communication as a sort of crutch in place of in vivo social interaction, which further isolates them.

More recently, however, researchers have acknowledged some potential benefits of online communication for individuals less comfortable engaging in face-to-face interaction (e.g., Madell and Muncer 2007). Socially anxious and withdrawn children tend to gravitate toward online communication relative to their more sociable peers (Valkenburg and Peter 2007). One likely reason for this is that online communication lacks much of the immediacy of in-person communication, which provides users with a greater sense of control (Madell and Muncer 2007). The traditional conversational tempo of face-to-face communication (i.e., immediate back and forth responding) is far less constrained online, and the lack of physical proximity offers an additional veil of control. In short, socially withdrawn children may find solace in some forms of online communication because they can take more time deciding what they want to say.

Another difference between in-person and online communication is anonymity. Of course, many forms of online communication are not anonymous (e.g., social media platforms). Nevertheless, the Internet is teeming with forms of online communication that permit a great deal of

anonymity (e.g., blogs, forums, chat rooms, etc.). There currently exists a proliferating culture of online gaming that allows individuals to interact anonymously with strangers from around the world. This anonymity may reduce the inhibitions of socially anxious children and provide them with a greater sense of interpersonal mastery (Kowert et al. 2014). However, excessive online gaming can come at a cost in the form of online gaming addiction (Kuss and Griffiths 2012). Moreover, among young adults, socially avoidant tendencies are associated with problematic media use, including excessive video gaming, online gambling, and consuming pornography (Nelson et al. 2016). Indeed, risk factors associated with obsessive, problematic gaming among children and adolescents (e.g., loneliness, depression, social anxiety) are comorbid with social withdrawal (Carrass et al. 2017). Overall, these findings indicate that measured use of online communication may offer some advantages for socially withdrawn children but should not be used as a replacement for in-person social interaction.

Conclusions

Scholars have suggested that humans are distinctively *ultrasocial* as compared to other species (e.g., Campbell 1983) and that this proclivity for social interaction has endowed humans with an evolutionary advantage for cooperation and colonization (Tooby and Cosmides 1996). Nevertheless, high sociability is evidently not an *essential* human trait, as a substantial portion of children and adults often refrain from interacting with others in favor of solitary activities. Current research continues to elucidate the motivations behind children's social withdrawal and the consequences that go along with different reasons for spending time alone in childhood.

Moving forward, the development of social withdrawal and its concomitants continues to be an active area of empirical inquiry. Researchers are continuing to address the clinical implications of excessive withdrawal and social anxiety. Interventions such as social skills training and peer

pairing have shown promise as effective techniques for promoting peer interactions and social competence among severely withdrawn children (see Coplan et al. [in press-a](#), for a recent review).

Perhaps most notably, insights into the potential benefits of solitude for children may reshape our understanding of the relative adaptiveness of socially withdrawn behaviors. Moreover, societal changes and advances in technology are constantly modifying our understanding of what it means to be *alone*. Opportunities abound for social interaction across an ever-changing plethora of media platforms, and children are increasingly exposed to such modalities earlier in their development. These changes in addition to social and cultural shifts will certainly impact children's beliefs and outcomes associated with social withdrawal.

Definition

Socialization refers to the ways in which new members of a group are assisted by older, more experienced, members to learn the values, attitudes, and appropriate behaviors of the group.

Introduction

Whenever they move into a new group, humans need to learn what is appropriate behavior in that group. This process of socialization goes on throughout the lifespan: Children learn how to behave in the home, at school, and while interacting with peers. As they become adolescents and adults, they move into new school settings and the workplace. As well they have to learn how to be marital partners, parents, and how, finally, to behave as an older member of society.

Most research has focused on socialization during childhood, as well as on the role of parents in that socialization. The focus on children reflects the fact that so much must be learned in this context, including regulation of emotions such as distress and anger, social competence, not

harming others, helping others, and understanding the perspective of others. The focus on parents reflects the fact that parents are biologically prepared to care for their offspring and that they are generally assigned the task by society. This entry will deal with children and parents, although it should be noted that other agents of socialization include teachers, peers, and siblings, where the same processes are operating.

Features of Socialization in Childhood

The Role of the Child

Socialization is not a one-way street, with the direction from parent to child. Children also influence their parents (Kuczynski and De Mol 2015). Thus it is not infrequently found that children's behavior produces change in the socializer's behavior. The change can be of either a positive or negative nature. A child's disobedience may lead to anger on the part of the parent, with that anger only serving to increase the disobedience. Or the disobedience may lead to a reconsideration of socialization strategies and choice of one that has a better chance of succeeding. The child's active role is reflected as well in the fact that children do not accept the teachings of the socializing agent as a whole. Values are not transmitted but, rather, are constructed as the child weighs a variety of choices (Bandura 1977). As children experience the negative impact of hurtful behavior on themselves, for example, they develop a sense of morality that includes not hurting others. As another example, children can change the values of their parents as they come in contact with other agents of socialization and other influences (Kuczynski and De Mol 2015).

The bidirectional nature of socialization is also evident in the fact that a given approach to socialization is not effective for every child. Effectiveness depends on a number of variables including the child's sex, age, temperament, mood, nature of the act, and previous history with the socializing agent (Grusec and Goodnow 1994). Fearful children, for example, are more likely to be negatively impacted by harsh parenting than are fearless ones (Bates and Pettit 2015). As other examples,

reasons for why a particular behavior is unacceptable must be matched with the cognitive abilities of the child, and the negative impact of physical punishment is lessened in countries where this form of punishment is more normative (Lansford et al. 2005).

Related to the fact that individual differences alter the impact of an intervention is the fact that a child's genetic makeup interacts with socialization experiences to produce different outcomes. As one example, Caspi et al. (2003) showed that child maltreatment was associated with subsequent depression, but only in individuals who had a short allele of the serotonin transporter (5-HTT) gene.

The Nature of Values

Values can be placed in two major categories. Intrinsic values include aspirations for personal growth, meaningful relationships, social responsibility, and physical health. Extrinsic values include financial success, physical attractiveness, and social recognition. Individuals who rate themselves higher on intrinsic values report greater feelings of psychological well-being than those who rate themselves higher on extrinsic values (Kasser and Ryan 1996). One explanation for this result is that people need to feel their behavior is self-determined rather than directed by others. Because extrinsic values depend on the reactions and evaluations of others they run counter to this basic need (Ryan and Deci 2000, 2017).

Schwartz (1992) has distinguished between self-transcendence and self-enhancement values. The former include tolerance, the protection of people and nature, and the preservation and enhancement of others. Self-enhancement values include status, prestige, control over people and resources, and personal success. The two sets of values are negatively correlated, with self-transcendence values generally valued more highly in many different countries.

Intuitive Morality

There is a substantial body of evidence that babies have a basic awareness of prosocial and moral values, that is, of concern for others and dislike of harm to others (Hamlin 2013; Warneken and

Tomasello 2015). As early as the first year of life infants show concern when others are distressed. As an example, they show pupil dilation, an indication of tension, when they see someone who needs help, with the tension reduced when help is received (Hepach et al. 2012). Infants at 6 months of age look longer at and are more likely to reach out to a puppet who helps another puppet trying to climb a hill than they look at and reach out to one who pushes the climber down the hill (Hamlin and Wynn 2011). This apparently innate predisposition is said to stem from ecological conditions faced by our ancestors that required collaboration in order to survive (Warneken and Tomasello 2015). Cooperative behavior, therefore, increased reproductive fitness. Moreover, cooperative behavior often required curbing selfish goals or even personal sacrifice, thereby facilitating the development of a moral sense, that is, a sense of what is right or proper. The fact that babies come equipped with prosocial tendencies, however, does not negate the central role of socialization which can shape those tendencies in a multiple set of directions.

Domains of Socialization

Adults socialize children in a variety of ways. Building on the work of Bugental (2000), Grusec and Davidov (2010) proposed five domains or contexts in which parenting could occur. Each domain involves a different need on the part of the child, a different relationship between parent and child, and different kinds of parenting action. The first two domains, protection and reciprocity, include the building of a caring and responsive relationship between parent and child. This relationship facilitates the acquisition of specific values that are learned in the remaining domains – control, guided learning, and observational learning/group participation.

With respect to the protection domain, humans have evolved to seek a safe haven and nurturing when they are in distress or danger. In turn, parents have evolved to provide that safe haven. Thus the child's attachment system and the adult's caregiving system are complementary and have evolved in parallel. When either system is activated child and caregiver move closer together so

that protection is enhanced (Bowlby 1969/1982). When the system is not activated children can explore their world, knowing that they have a secure base to which they can return.

Appropriate responses to children's distress change with age. Holding is suitable for a baby. Young children may profit from a discussion of emotions. Ultimately the goal is to teach children how to cope with distress on their own. "Not-too-nice parenting" (Bates and Petit 2015) is one way in which this is accomplished. In this approach to socialization, parents are not excessively sensitive and responsive (see, for example, Degnan et al. 2008), and they respond to children's emotions by listening, accepting, querying, and complying rather than engaging in overindulgent helping and comforting or even simple distraction (Morris et al. 2011).

One important outcome of caregiver reactions to children's distress is the development of behavior that is helpful and comforting to others. Parents who try to help their children alleviate feelings of distress, or who help them find ways to problem solve and deal with challenging issues, facilitate children's coping with their own emotions, including the empathic distress they feel for others. In this way, children are able to act prosocially in response to the negative emotions of others rather than being overwhelmed and immobilized by their own distress (Eisenberg 2010). Toddlers of mothers who were supportive were found to comfort an adult who had "accidentally" hurt herself by, for example, patting her or getting the mother's attention. Children with mothers who were less supportive tended to go to the mother, touch her, hold their arms out to be picked up, or buried their heads in her lap (Eisenberg et al. *in press*).

The next domain, reciprocity, emerges from the human tendency to reciprocate favors, a characteristic that, like protection, contributes to survival and reproductive success (Trevvarthen et al. 1999). Reciprocity occurs not only with kin but with unrelated individuals as well. In this domain, the relationship is one of equality where children have an equal say in how the interaction will proceed. When parents respond to their children's reasonable requests they set up conditions where

their children, in turn, will respond to their parents' (reasonable) requests. Most importantly, this compliance is willingly given rather than a result of parental pressure. Play is one example of a reciprocal interaction, provided socializing agents refrain from assuming a didactic role. When play is jointly managed, and there is shared positive affect between adult and child, children show higher levels of peer competence and prosocial behavior as well as less antisocial behavior (for example, Lindsey et al. 2010).

In the control domain, children experience consequences in the form of discipline or punishment for antisocial actions and reward for prosocial actions. Additionally, they need to internalize the values associated with those actions, that is, believe that those actions are intrinsically motivated or inherently correct. Otherwise, they would have to be under constant surveillance to make sure they behaved in accord with societal rules and regulations. Researchers have demonstrated that internalization is most likely to be achieved when agents of socialization use a combination of punishment and reasoning, make rules clear, and enforce them consistently (Grusec and Goodnow 1994). Additionally, the punishment must be just sufficient to capture the child's attention and just sufficient to motivate a change in behavior. Otherwise, positive action can be attributed to external pressure rather than an understanding of why one particular action is more appropriate or more moral than another (Grusec and Goodnow 1994; Grusec and Davidov *in press*). In the former case not only is compliance with societal dictates not given willingly, but it can lead to reactance, that is, a desire to do the opposite of what is required. Reactance occurs because of the human need for autonomy or choice which is thwarted when too much external pressure is applied (Ryan and Deci 2017). Also to be noted is that discipline is most effective when it is administered by parents who have a positive and warm relationship with their children (Grusec and Goodnow 1994).

Punishment involves a variety of consequences, including verbal disapproval, withdrawal of love, withdrawal of material rewards and privileges, time-out, and corporal

punishment. Considerable debate has centered around the question of whether corporal punishment in the form of spanking or hitting on the buttocks or extremities with an open hand is harmful (let alone ineffective). In a review of a considerable body of research, Gershoff and Grogan-Kaylor (2016) reported strong evidence that corporal punishment is not only associated with, but leads to, children's externalizing problems.

Socialization in the control domain has its challenges. For example, it often occurs in the context of high levels of arousal on the part of both child and parent. When parent and child are angry it can be difficult for the parent to function effectively or for the child to listen and accept. The guided learning and observational learning domains present fewer of these sorts of challenges.

Socialization in the guided learning domain is important because humans have limited physical prowess and so, in order to survive, they must rely on the learning of intellectual skills. The human capacity for language allows for the teaching of complex skills and the relatively long period of dependence the young have on their parents allows time for this teaching. In this domain, the relationship is one between teacher and student. Importantly, teaching must be done within the child's zone of proximal development (Vygotsky 1978), so that teachers help children solve problems they are not quite ready to solve independently, with constant alterations to match the child's changing skill level. Eventually, a shared understanding is achieved and the particular lesson is said to be internalized. The process is an interactive one, with discussion and exchange of views leading to better mastery of the task (Haden et al. 2001). In this domain, children can learn about values and associated actions, as well as about the nature of emotions and how to express and manage them (Denham et al. 2015).

Guided learning is an important element in moral development. Even very young children engage in conversations about moral values with their parents, often taking the lead in these conversations (Wright and Bartsch 2008). The most successful conversations are those where parents elicit their children's opinion and check for

understanding, as well as being supportive and not negative (Walker et al. 2000). Parents who are high in generativity, who see the training of future generations as an important part of their functioning, are particularly likely to engage in guided learning, that is, story-telling that deals with suffering, growth, and kindness of others (McAdams 2004).

Finally, the group participation domain includes modeling of others' behavior as well as participation in positive social behavior with other group members. Adoption and valuing of group practices and symbols is important from an evolutionary perspective because it identifies the individual as a member of the in-group, where good treatment is more likely (Brewer and Gardner 1996). These practices are very frequently learned through observation of others, a procedure Bandura and Walters (1963) identified as the basic form of human learning. Through watching others, children learn values and how to behave (or not to behave) in accord with those values. Socializing agents, in turn, try to control the models to which their children are exposed by selecting the neighborhoods in which they live, monitoring their access to media, and encouraging their interaction with peers whose values they consider appropriate.

As well as learning about appropriate behavior through watching others, children also learn it from engaging in routines and rituals. Examples of routines are helping out around the house or engaging in value-related activities such as volunteer work. Social conventions such as ways of dressing and table manners are also carried out in a routine way so that, with repetition, they come to be viewed simply as the way things must be done. Rituals are activities such as holiday celebrations or family get-togethers that reflect group membership and values, and thereby enhance feelings of being part of the group and engaging in activities with the group.

Conclusion

Effective socialization involves both a positive relationship with the agent of socialization as

well as the learning of specific values and standards of behavior. There is no one effective way in which to help children become well-functioning members of their social group. Parents act as protectors, playmates, disciplinarians, teachers, and fellow group members and need to act in accord with that particular role. Whichever role they need to assume depends on sensitivity to the child's current state.

Definition

The heated controversy that followed the publication of Wilson's book *Sociobiology: The New Synthesis* and involved Wilson himself as well as critics in biology and the social sciences.

Introduction

More than 40 years ago, in 1975, biologist Edward Osborne Wilson (► [E. O. Wilson](#)) published his book *Sociobiology: The New Synthesis*. It was an attempt to bring together research on animal social behavior in one place, consolidating theory and empirical evidence from several subfields in biology, including ethology, population biology, and zoology. What later led to the “sociobiology wars,” or the “sociobiology debate,” was not Wilson's aim to foster cross-species comparisons of social behavior with that book and thereby advance the study of animal behavior. Even though contained in only the last of a total of 27 chapters, titled: “Man: from sociobiology to sociology,” it was rather his explicit aim to extend this approach to human behavior – and his ambition to thereby lay the ground for a potential integration of the social sciences into the field of evolutionary biology. This appeared justified given the seemingly gradual distinction of human from animal behavior (Schnettler 2010). In this entry, we will take a look at what was at issue in the ensuing debate, what it meant for the integration of evolutionary and social sciences in the upcoming years, and how similar issues have been debated and applied in more recent years.

Dissecting the Sociobiology Debate

Based on many interviews and her reading of the publications and other written exchanges between the relevant protagonists, Swedish sociologist and historian of science Ullica Segerstråle provides arguably the most in-depth account of the sociobiology debate in her book *Defenders of the truth: The Battle for Science in the Sociobiology Debate and Beyond* and in a number of journal articles

(e.g., Segerstråle 2000, 2001). She dissects how the exchange between Wilson and his critics got started and why the sociobiology debate, which “raged throughout the 1970s and 1980s” (Laland and Brown 2002, p. 4) turned, at times, so acrimonious and personal. One of the most dramatic events that illustrates well how heated the debate had gotten was when at “the 1978 meeting of the American Association for the Advancement of Science in Washington [...] a group of activists from the International Committee against racism poured a pitcher of ice-water in Wilson’s neck, shouting: ‘Racist Wilson, you can’t hide, we charge you with genocide!’ and ‘Wilson, you are all wet!’” (Segerstråle 2001, p. 549).

As the description of this scene illustrates, one of the central and loudly voiced accusations against Wilson was that he followed a conservative political and even racist agenda with his sociobiology. These and other accusations and criticisms (e.g., naïve adaptationism, genetic determinism) were originally brought forward by his Harvard colleagues, famously including Stephen J. Gould and Richard Lewontin (► [Richard Lewontin and Stephen Jay Gould](#)), who were among the members of the critical Sociobiology Study Group which at some point published a critical letter about Sociobiology in the *New York Review of Books* (Segerstråle 2001). From her empirical material, Segerstråle (2001) concludes that it was in fact a mix of motives that fueled the sociobiology debate. These were introduced by what she called two different types of “Trojan horses,” a term that she uses to highlight that, in the sociobiology wars, moral goals were hidden behind scientific arguments and vice versa: “On the one hand, the protagonists used political rhetoric to generate attention for their own scientific agenda. On the other hand, and with an eye on historical misuses of Darwinism in the form of Social Darwinism, they used scientific arguments to thwart sociobiology and thereby reduce the potential risk of a renewed political instrumentalization of evolutionary theory by others” (Schnettler 2010, p. 19; Segerstråle 1986).

Given the extremely politicized atmosphere of the sociobiology debate, it might come with no surprise that the reactions to sociobiology

included some distortions of Wilson’s writings and that the criticisms were therefore at least in part unjustified (Schnettler 2010; Segerstråle 2000). A quote of one of the few scientists at the time who took the middle ground in the sociobiology debate, John Maynard Smith (Laland and Brown 2002), illustrates how polarized the opposing protagonists in the debate had gotten: “I find that if I talk to Dick Lewontin or Steve Gould for an hour or two, I become a real sociobiologist, and if I talk to someone like Wilson or Trivers for an hour or two, I become wildly hostile to it” (interview excerpt, quoted in Segerstråle 2000, p. 241).

Evolutionary Psychology, the New Sociobiology?

Despite the heated atmosphere of the sociobiology debate, scientists were able to continue working on animal and human behavior from within an evolutionary framework somewhat under the radar by using different field labels. New fields like ► [human behavioral ecology](#), evolutionary psychology, and ► [dual inheritance theory](#) had emerged that could all be considered descendants of sociobiology (Laland and Brown 2002; Schnettler 2010). Of these, evolutionary psychology, which had been established as a new paradigm in the late 1980s and early 1990s, became quite popular but in the following years drew some of the same criticism as sociobiology had drawn earlier, yet in a quieter and somewhat less politicized way (ebd., see also Freese 2002).

Sociobiology and Sociology

It was not only from within his own discipline and even university department that Wilson was criticized. Strong criticism was also expressed by the social sciences, not least because of Wilson’s ambition to ultimately subsume the social sciences as a branch of biology (Laland and Brown 2002). The reservations against sociobiology, in fact against any biological explanation to human behavior, have long persisted in sociology. This

only recently started to change. Now it was suddenly sociology that got increasingly criticized for disregarding new developments in the evolutionary theory of human behavior (► [Crisis in Sociology](#)). Some even went so far as to diagnose sociology with a veritable “biophobia” (Barkow 2006, p. 10). And this neglect of biological approaches to human behavior was also increasingly seen problematic from within sociology (e.g., Freese et al. 2003; Schnettler 2010). In recent years, however, sociology has increasingly opened toward integrating biological explanations into their explanatory repertoire as labels of new fields of study like “sociogenomics,” “neurosociology,” or “evolutionary sociology” illustrate (Conley et al. 2014; Machalek and Martin 2004; von Scheve 2011).

Definition

Sociocultural theories of violence focus on how violence can be explained through a combination of features of the cultural environment and aspects of specific social structures and institutions.

Introduction

Violence in its myriad forms is an endemic feature of human societies. Globally, in 2012 approximately 437,000 individuals were the victims of homicide (United Nations Office of Drugs and Crime 2013), just under 40,000 were casualties of armed conflict (Pettersson and Wallensteen 2015), and many more individuals suffered from the consequences of nonlethal interpersonal and collective violence. Rates of violence do, however, vary quite substantially between nation-states, different regions, and different neighborhoods. They also vary over time: violence is more common during some historical periods compared to others (Eisner 2014). One challenge for theories of violence is to explain not only why violence occurs and the contextual factors that make violence more or less likely but also to account for the substantial *variation* that is found in violent offending in different locations and during different time periods. Sociocultural theories of violence are especially salient for addressing this particular challenge (Durrant and Ward 2015). Very broadly speaking, two different types of explanation have been developed by social scientists to account for regional and historical variations in violent offending. First, *cultural approaches* focus on how specific beliefs, norms, values, and attitudes might influence the expression of violence. Second, *social-structural approaches* explore how social-structural characteristics such as poverty, inequality and political legitimacy, and particular *social institutions* shape the expression of violence in society. In order to keep this review to a manageable length, the focus will be on theoretical attempts to explain interpersonal violence; thus sociocultural approaches to understanding collective violence such as war, terrorism, and genocide will be excluded.

Cultural Approaches

There is no universally agreed upon definition of “culture,” but broadly speaking culture refers to shared patterns of norms, values, beliefs, practices, and institutions that help to distinguish

among different social groups. These shared patterns, furthermore, arise through a process of social or cultural learning as individuals who are embedded in particular social groups acquire the relevant values, norms, and practices of those groups during their development. Although clearly developmental outcomes are shaped by both biological and cultural factors and their interactions, many social scientists focus on the way that the acquired values, norms, beliefs, and practices can influence behavior, including the expression of violence.

Social Learning Theory

The central idea of social learning theory is relatively straightforward: humans acquire their specific attitudes, beliefs, norms, and behaviors through a process of social learning. Individuals learn not only from their own experiences with the world but also through the observation of others – or what Albert Bandura (1973) terms *vicarious learning*. Whether or not a given behavior is learned by an individual depends both on the outcome of that behavior and, for vicarious learning, on the status of the observed individuals (who are referred to as “models”). Behavior is more likely to be learned if it (a) results in (or is observed to result in) positive outcomes for the individual and (b) if the observed individual is high in status and shares similar characteristics to the observer. Social learning explanations have played a prominent role in understanding the development of aggression and violence (Akers 1977; Bandura 1973).

In a classic study in social psychology, Bandura and colleagues demonstrated that when young children observed an adult engaging in aggressive behaviors toward a large, inflatable “bobo” doll, then they were more likely to behave aggressively toward the doll – including imitating the very same behaviors observed in the adults – than were children who had witnessed adults engage in nonaggressive actions (Bandura et al. 1961). These studies and others like them suggest that aggressive acts can be learned through the observation of others’ behaviors. The idea that violence and other criminal behaviors arise through social learning from others also features

in several prominent criminological theories. Sutherland's (e.g., Sutherland and Cressey 1974) idea of differential association is premised, for instance, on the idea that criminal behavior is essentially learned and that individual differences in criminal behavior arise through different patterns of associations with others. Similarly, Akers (1977) argued that crime is learned through social interactions with others such that in social environments where criminal behavior is positively reinforced, it is more likely to be repeated.

A social learning approach to understanding violence has been particularly relevant in explaining how growing up in a family environment with high levels of violence can subsequently elevate the risk for aggressive and violent behavior. The *intergenerational transmission of violent offending* is now well documented as children who are exposed to violence in the home are more likely to engage in violent offending than those who do not. This suggests that, in part at least, their violent behavior is the result of social learning processes (Van de Wijer et al. 2014; Widom 1989). There is also an accumulating body of evidence that suggests that exposure to violent films, video games, and other violent media elevates the risk for aggression and violence as a result of social learning (e.g., Anderson et al. 2015), although others have disputed this conclusion (e.g., Ferguson 2015) and media effects may be relatively small in magnitude. In sum, the human capacity for social learning is an important characteristic that can help us to understand the development of violent behavior. Social learning theory also provides the theoretical base that other sociocultural explanations rely on to account for variation in offending across time and space.

Subcultures of Violence Theory

If violent behavior is, in part, socially learned from interactions with others, it follows fairly straightforwardly that some social environments may promote the development of violence more than others. In particular, social environments in which violence is more frequent and in which attitudes toward violence in particular situations are more positive should foster the development

of norms, values, and behaviors that are favorable to the use of violence. According to Wolfgang and Ferracuti's (1967) *subcultures of violence theory*, there exist certain social groups or subcultures in society which differ from the culture of mainstream society. In these social groups – which are typically more socially disadvantaged – violence can be viewed as a legitimate or even obligatory response to particular social situations, especially those that entail the maintenance of respect or social status. The development of these subcultures of violence is strongly shaped by prevailing social-structural features of society but is subsequently acquired by members of the subculture through social learning processes.

The subcultures of violence theory have been further developed in the work of Elijah Anderson (1994, 1999) who argued that the high rates of violence among, in particular, socially disadvantaged African-American males can be attributed to their inculcation into what he refers to as the “code of the streets” “which amounts to a set of informal rules for governing interpersonal public behavior, including violence” (Anderson 1994, p. 82). Of particular note is the way that this “code” dictates (or, at least, socially endorses) the use of violence in response to threats to status or “face”: individuals inculcated into the code of the streets learn to adopt a tough, no-nonsense, persona and the willingness to use violence to resolve disputes and to respond to social threats. Why has this “code” developed and how might it potentially be “adaptive” in particular social contexts? According to Anderson (1999), the specific set of attitudes, norms, and practices relating to violence emerges as a response to social-structural contexts characterized by high levels of poverty, low unemployment, and a lack of reliable third-party reinforcement of social norms (e.g., the police). As a result, status becomes a precious commodity, and individuals are required to resolve their own disputes and conflicts. The threat and use of violence, thus, becomes an effective method of obtaining status and resources. Because children develop in this particular cultural milieu, they come to learn rules, norms, and beliefs that are conducive to the use of violence in

particular contexts, thus perpetuating this subculture of violence.

Support for Anderson's subculture of violence theory has come from a number of studies. Stewart and Simons (2010), for example, conducted a longitudinal study of African-American youth and their caregivers in low-income neighborhoods in Iowa and Georgia. The self-reported violence of youth was measured at two time points along with a measure of neighborhood street culture completed by caregivers which tapped into the key constructs of Anderson's "code of the streets" (e.g., "When someone disrespects, it is important that you use physical force or aggression to teach him or her not to disrespect you," and "People will take advantage of you if you don't let them know how tough you are"). The results largely supported Anderson's thesis: individuals who lived in neighborhoods where the code of the streets was more strongly endorsed were more likely to report aggressive and violent behavior, after controlling for other relevant factors. Interestingly, although the code of the streets was initially developed in the specific context of disadvantaged African-American communities in the United States, it has since been extended to other cultural contexts such as street children in the Ukraine (Naterer 2015) and socially disadvantaged communities in Scotland (Holligan 2015). This suggests that something like the set of values, norms, and behaviors that are reflected in the "code of the streets" may be a fairly robust human (especially male) response to a particular set of social contexts such as those characterized by a weak criminal justice system and a lack of legitimate routes to obtain status. A very similar idea is presented in culture of honor thesis developed by Nisbett and colleagues (1993; Nisbett and Cohen 1996).

The Culture of Honor Thesis

Regional differences in homicide rates in the United States are well recognized. In particular, homicide is more prevalent in the Southern, compared to the Northern states. Why might this be the case? Various factors have been proposed over the years including differences in poverty, income inequality, temperature, and the legacy of slavery.

However, according to the culture of honor thesis, the difference in homicide rates can be largely accounted for by cultural factors (Nisbett 1993; Nisbett and Cohen 1996). The culture of honor thesis rests on three key foundations. First, although the human capacity for aggression and violence may be the result of evolutionary processes, its expression is strongly shaped by specific ecological contexts. Of particular relevance to the culture of honor thesis is the idea that individuals whose livelihood is primarily based around the herding of domestic animals like sheep, pigs, and cattle are more likely to use violence and the threat of violence to maintain their status and reputation compared to individuals who primarily engage in farming. Because the wealth of herders is invested in their livestock, they face a greater risk of their livelihood being stolen by others. They are also more likely to live in regions that are sparsely populated and hence not readily subject to the rule of law. This means that herders need to be able to resolve their own disputes and, ideally, prevent theft from others by cultivating "a posture of extreme vigilance toward any act that might be perceived as threatening in any way, and respond with sufficient force to frighten the offender and the community into recognizing that they are not be trifled with" (Nisbett 1993, p. 442). Farmers, on the other hand, according to Nisbett and Cohen (1996), are more likely to form tight knit and cohesive communities involving the sharing of resources and to live in regions where the effective rule of law is more likely to be in place.

The second component of the culture of honor thesis rests of the particular pattern of immigration from the United Kingdom to the United States. The Northern states of the Eastern Seaboard were primarily settled by farmers from England, Holland, and elsewhere, while the Southern states attracted more settlers from Scotland and Ireland whose economy was largely based on herding. These settlers relocated to southern and western frontiers and continued a livelihood largely based on herding and hunting (Nisbett 1993). These different settlement patterns meant that cultural values relating to violence and honor also differed in the different regions: in the American South, a

culture of honor persisted, whereby individuals (mainly men) believe that violence is the appropriate – perhaps expected – response to threats to the reputation of the self or family. The third component of the culture of honor thesis rests on the assumption that these particular values, norms, and beliefs are more common today in the American South as a result of their ongoing socialization in subsequent generations.

The culture of honor thesis, then, predicts that certain forms of violence, and norms related to violence in particular contexts, will be more common in Southern regions of the United States. In particular, it is argued that dispute-related homicides (as opposed to purely instrumental homicides such as might occur in robberies) will be more prevalent. What evidence is there in support of this idea? Generally speaking it appears that regional patterns in dispute-related homicide support this hypothesis. Such homicides are more prevalent in Southern states and in locations where there is a relatively greater proportion of white men who were born in the South and hence likely to be inculcated with the culture of honor (e.g., Ousey and Lee 2010). Moreover, counties with a greater proportion of Scottish and Irish immigrants in the nineteenth century have higher rates of dispute-related homicides (Baller et al. 2009). Experimental research also supports the idea that Southern men possess different norms regarding the appropriate response to insults and threats and demonstrate more aggressive behavior in response to such threats along with heightened physiological arousal (Cohen et al. 1996).

Although the culture of honor thesis was developed to explain regional differences in the use of violence in the United States, the underlying mechanisms that account for the different use of violence are likely to be more widely applicable. The use of violence can often be a viable strategy for obtaining desirable outcomes, but it also entails risk. Individuals who are more likely to use violence also place themselves in contexts where they are more likely to experience harm themselves from the retaliation by others. Thus violence is a context-dependent strategy: to the extent that values, norms, and beliefs regarding violence shape its use, these should be more

common in certain contexts rather than others. According to a recent model developed by Nowak et al. (2016), honor cultures reliably emerge in particular social contexts: when institutions that regulate third-party conflicts (e.g., an effective criminal justice system) are absent. Under such contexts, the use of violence is effective despite the costs that it might entail to individuals. The culture of honor thesis, thus, might reflect more general processes that emerge in a range of different cultural contexts even though the main focus has been in explaining regional differences in the United States (also see Daly 2016, for a thoughtful critique of the culture of honor thesis as applied to differences in homicide rates in the United States).

The Civilizing Process

The prevalence of violence also varies – and varies quite substantially – over time. This is most evident from the precipitous fall in homicide rates in Europe over the last 500 years, from an average of around 30 homicides per 100,000 people in the fifteenth century to a mean of around 1 per 100,000 in the twentieth century – a 30-fold decline (Eisner 2014). Homicide rates have also fluctuated quite dramatically in many Western countries over the last 50–60 years. In the United States, for instance, homicide rates that were low in the 1950s gradually increased in the 1960s and 1970s, reaching a peak in the late 1980s and early 1990s before declining again (e.g., Farrell et al. 2014). If we accept that homicide rates are a pretty reliable general indicator of the overall prevalence of violence in society, then it is clear from the historical record that violence is more common in some historical periods compared to others.

There have been many attempts to explain patterns of violence (and other types of crime) over time, with no widely accepted set of explanations (see Eisner 2013, 2014; Pinker 2011). It is likely that there are many factors relevant to understanding temporal patterns in violence, but the sociologist Norbert Elias' (1939/2000) theory of the “civilizing process” provides a useful starting point. The main interest of Elias was to account for changes in “civilized” behavior such as those relating to manners and personality over

time, but the key processes that he emphasized are also broadly relevant for understanding shifts in the use and acceptance of violence.

The starting point for the shift in violence in Western society is linked to two key social-structural changes (Eisner 2014). First, the expanding power of the state meant that increasingly disputes were resolved by legitimate third parties rather than individuals and their families, reducing the need for individuals to take matters into their own hands. Second, the expansion of trade and the market economy created dense networks of exchange that encouraged reciprocal interdependencies among people. In turn, these changes promoted the importance of self-control and a growing distaste for the use of force to resolve conflicts. For Elias, these changes first occurred among elites. Then, as others imitated the beliefs and practices of high-status individuals' relevant norms, beliefs and attitudes spread throughout the population, leading to wholesale shifts in violent-related norms, values, and beliefs and a decline in violent crime. Although such shifts are theorized to occur relatively slowly to account for the decline in homicide in Europe since the fifteenth century, changes in cultural values may also occur more rapidly and can potentially account for the fluctuations in violent crime witnessed in many Western countries over the last 50–60 years (Eisner 2014; Pinker 2011).

Social-Structural Approaches

There is an extensive amount of research that has examined the social-structural correlates of violence, with a particular focus on homicide. In an early study conducted in the United States, it was found that resource deprivation, population structure (size and density of population), and divorce rate significantly predicted variation in homicide rates across states, cities, and metropolitan areas (Land et al. 1990). Subsequent research has uncovered a range of social-structural correlates with poverty and income inequality, the ones that most reliably predict variation in homicide rates (e.g., Nivette 2011), although a range of other factors such as population structure and growth

are also important (Nivette 2011). Two prominent theoretical traditions in criminology – social disorganization theory and strain theory – have been employed to account for these findings and are useful in helping us to understand the social-structural factors that contribute to violence in society.

Social Disorganization Theory

According to the central tenets of social disorganization theory, neighborhoods and communities in which there is significant social disadvantage and a high turnover of residents, which are ethnically diverse, tend to be less socially cohesive because there is a lack of agreement over appropriate norms and values for the informal control of behavior. Crime rates remain high over time even in the face of substantial changes in the population of such communities as, via social learning, individuals acquire the norms, attitude, and values that are characteristic of such communities. Robert Sampson's (Sampson 2012; Sampson et al. 1997) theory of *collective efficacy* represents the most prominent contemporary approach within the social disorganization tradition. The term "collective efficacy" was developed to characterize the degree of social cohesion that is found within a given community. Communities that are high in collective efficacy are characterized by individuals who share certain norms, values, and beliefs about behavior and are willing to enforce these in order to maintain social control and to reduce violence. Thus, "the differential ability of neighborhoods to realize the common values of residents and maintain effective social controls is a major source of neighborhood variation in violence" (Sampson et al. 1997, p. 918).

The theory of collective efficacy can, therefore, in principle, help us to understand some of the variation in violent offending that is found between neighborhoods or communities. A number of studies in the United States and elsewhere have largely supported the underlying assumptions of collective efficacy theory (Armstrong et al. 2015; Mazerolle et al. 2010; Sampson et al. 1997; Sutherland et al. 2013). For example, Sampson et al. (1997) conducted a survey of over 8700 residents in 343 neighborhoods

in Chicago measuring participants' perceptions of both collective efficacy and the frequency of violence in the neighborhood in which they reside. Results indicated that neighborhoods varied significantly in terms of perceptions of collective efficacy which, in turn, was significantly associated with the prevalence of neighborhood violence. In a more recent study by Sutherland et al. (2013) involving 60,000 individuals in 4700 neighborhoods in London perceptions of neighborhood collective efficacy significantly predicted police recorded rates of violence crime, although the relationship was relatively small in magnitude. It is reasonable to conclude at this stage that a community's level of social cohesion or collective efficacy does appear to have an influence on the prevalence of violence in that community and can potentially explain variations in the prevalence of violence that is found among neighborhoods and communities. Sampson (2012) has also argued that shifts in collective efficacy over time can also account, in part, for changes in the rate of violent crime over time and may be one factor that is implicated in the overall decline in violent offending in the United States since the early 1990s.

Strain Theory

The sociologist Robert Merton (1938) argued that crime, in general, largely emerged in response to particular social-structural and cultural contexts. In particular he highlighted how the cultural values underpinning the "American dream" of economic success and prosperity were not available to everyone in American society as many individuals are impeded from fulfilling this vision due to poverty and barriers to social mobility. As a result, Merton argued, criminal behavior – including the use of violence – can often be viewed as an adaptive strategy to mitigate the strain brought about by the failure to achieve culturally prescribed goals. This basic idea has been subsequently developed by criminologists working in the strain tradition, including Agnew (1992, 2007) and Messner and colleagues (2012; Messner and Rosenfeld 2013).

Agnew's *general strain theory* builds on earlier theoretical work in the strain tradition by

emphasizing how an individual's response to strain can vary depending on a range of factors including the nature of the strain (whether it is unjust, its magnitude or impact, and how controllable it is) and their individual perceptions of that strain. For Agnew (1992), although social-structural factors are an important distal source of strain, it is the experience of negative relationships with others that can result in negative emotional states such as anger and frustration which, in turn, can lead to various forms of violent and non-violent offending. Although general strain theory has been employed to explain offending in general, Agnew (2007) has also argued that it can account for both individual and community variation in violent offending. More recently, Agnew has expanded the scope of his theory to other forms of violence, including terrorism (Agnew 2010).

Messner's *institutional anomie theory* following the pioneering work of Merton highlights the way in which American cultural values and the institutional structure of American society reinforce a set of culturally prescribed values focusing on economic success and prosperity while at the same time excluding many individuals in society from their attainment. The relatively high rates of crime that are found in American society thus are the result of "... dominant cultural values that extol the virtues of competitive individual achievement and wealth accumulation at the expense of values that emphasize noneconomic forms of achievement, collective solidarity, and the common good" (Messner et al. 2013, p. 411). Thus, one central idea of institutional anomie theory is that certain types of "institutional configurations" (Messner 2012, p. 11), particularly those that elevate the role of the economy above all else, are more conducive to generating anomie which, in turn, elevates the risk for violence.

Conclusions

Understanding violence requires that we consider a range of different theoretical approaches drawn from different levels of analysis. Ultimately, in order to provide a complete explanation, we

need to consider (a) the evolutionary functions and history of violence, (b) how violence emerges during human development, (c) the proximal psychological and physiological mechanisms that give rise to violent behavior, and (d) the specific situational contexts that make violence more likely (Durrant and Ward 2015). Because the prevalence of violence varies quite substantially among different neighborhoods, communities, regions, and countries, over time we also need to consider how features of the cultural and social-structural environment make violence more or less likely. A number of specific cultural and social-structural explanations for violence have been considered in this article.

Cultural approaches to explaining violence focus on how particular norms, values, practices, and beliefs can influence the likelihood of violence. Thus, according to the subcultures of violence hypothesis, some subcultural groups hold norms that are favorable to the use of violence, especially in situations that involve a threat to reputation or status. Similarly, according to the culture of honor hypothesis, regional variations in violence in the United States can be explained, in part, due to cultural differences in beliefs about normative responses to threats to honor and reputation that have their historical origin in herding communities in the United Kingdom. More generally, cultures of honor tend to arise when there is a lack of third-party enforcement of social norms, resulting in the need for individuals to use violence as a way of settling disputes and deterring victimization. Ultimately the cultural factors that can influence violence arise through the social learning on norms, values, and practices from relevant individuals in the community.

Social-structural approaches to explaining violence focus on the particular role of social institutions. Theories that have emerged from the social disorganization perspective highlight the importance of social cohesion or collective efficacy in accounting for neighborhood variation in violent offending. Work in the strain tradition emphasizes the way that social institutions affect individuals in ways that can make offending more likely by increasing strains. Agnew's general strain theory focuses more on individual differences in

response to strains, whereas Messner's institutional anomie theory attempts to account for the high rates of violent crime in American society by noting the highly competitive, economically oriented nature of America's dominant cultural values and social institutions.

Definition

The *self-esteem* refers to a person's appraisal of his or her value. *Global self-esteem* denotes a global value judgment about the self, whereas *domain-specific self-esteem* involves appraisals of one's value in a particular area. Self-esteem is, by definition, a subjective judgment and, thus, may or may not directly reflect one's objective talents or accomplishment (Leary and Baumeister 2000). Importantly, self-esteem is an affectively laden self-evaluation. *Self-evaluations* are assessments of one's behavior or attributes along evaluative dimensions (e.g., good-bad). Some self-evaluations are dispassionate, whereas others are affectively laden. There are two monitoring systems – one immediate and one long term – corresponding to the common distinction between state and trait self-esteem. *Trait self-esteem* is a person's long-term, typical, affectively laden self-evaluation. *State self-esteem*, also called *self-esteem feelings*, refers to a person's affectively laden self-evaluation in a particular situation (Heatherton and Polivy 1991). The self-esteem system is essentially a *sociometer* that monitors the quality of an individual's *interpersonal relationships* and motivates behaviors that help the person to maintain a minimum level of acceptance by other people (Leary and Downs 1995). Although considerable research has identified types of events that raise and lower self-esteem, sociometer theory offers a novel perspective on why these particular factors have their effects. According to the theory, things that affect self-esteem do so via their perceived association with *social inclusion* and *exclusion*.

Introduction

The fact that people are highly and pervasively motivated to protect and enhance their self-esteem suggests that self-esteem must somehow be linked to some important and highly desirable outcome. This entry focuses on two pertinent issues in the literature on *sociometer theory* on self-esteem.

- (A) What is the self-esteem and what is the function of the self-esteem?
- (B) What is the sociometer theory and what is the extension of sociometer theory?

The Nature of Self-Esteem and Its Function

The human organism is characterized by a basic need to belong – a fundamental motivation to form and maintain at least a handful of meaningful social attachments. The power and importance of this motivation are sufficient to think that people might well possess an internal meter to monitor such relationships. Indeed, when something is extremely important to an organism's well-being, internal mechanisms tend to develop for monitoring it. For example, pain serves to signal the possibility of damage to the body, and hunger and satiety monitor how well the person is obtaining nutrition and sustenance (Leary and Baumeister 2000; Zhang and Cao 2011; Zhang and Li 2009).

The central tenet of sociometer theory is that the self-esteem system monitors the quality of an individual's actual and potential relationships – specially the degree to which other people value their relationships with the individual. People do not always seek to be explicitly accepted but rather relational appreciation – the sense that other people regard their relationships with the individual as valuable, important, and close. When low relational evaluation, and particularly relational devaluation is experienced, the sociometer evokes emotional distress as an alarm signal and motivates behaviors to gain, maintain, and restore relational appreciation (Leary and Baumeister 2000).

According to Leary and Baumeister (2000), self-esteem not only signals one's relational value in the immediate situation but reflects the general outlook for relational appreciation and social belongingness in future encounters and relationships. There are two monitoring systems – one immediate and one long term – correspond to the common distinction between state and trait self-esteem. State self-esteem monitors the

person's current relational value and, thus, the degree to which he or she is likely to be accepted and included versus rejected and excluded by other people in the immediate situation (Leary and Downs 1995). The state self-esteem system monitors the person's behavior and social environment for cues relevant to relational evaluation and responds with affective and motivational consequences when cues relevant to exclusion and detection. Trait self-esteem, in contrast, involves the assessment of the degree to which one is the sort of person who generally will be valued by desirable groups and relationship partners. It is a subjective sense of one's potential for social inclusion versus exclusion over the long run.

Several properties of the self-esteem system can be proposed on the basis of the sociometer function. First, the system should be highly sensitive to indications that one's social inclusion or acceptance is in danger. Second, it should operate continuously at an unconscious or preattentive level so that relational devaluation would be detected no matter what else the person is doing. Third, assuming that most people have at least the minimum amount of social acceptance they need most of the time, the system should be more sensitive to relational devaluation than to relational appreciation. Even though social inclusion is of paramount importance to their physical and psychological well-being, people do not possess the cognitive capacity to constantly monitor other's reactions to them at a conscious level. Thus, a system for monitoring relational appreciation and devaluation would have to function automatically, probably at a preconscious level (Cherry 1953; Schneider and Shiffrin 1977). The primary advantage of automatic system is their efficiency. Assessing real and potential belongingness is important to human well-being, but to consciously think through the implications of all interpersonal transactions and social experiences to assess their implications for belongingness would interfere with the person's ability to process other information. Therefore, a mechanism for monitoring one's global desirability for groups and relationships would need to be automatic.

The Mating Sociometer

In an extension of sociometer theory, Kirkpatrick and Ellis (2001, 2006) proposed that there were multiple sociometers associated with functionally distinct social-psychological systems and that these sociometers had multiple functions (in terms of guiding day-to-day decision-making and behavioral strategies). One of these proposed functions was guiding adaptive relationship choices.

In the context of developing social relationships in different social domains (e.g., the mating domain, the friendship domain, the work domain), individuals faced the problem of adaptively calibrating their levels of aspiration. Natural selection should act against individuals who either invested too heavily in social relationships that were substantially lower in value than they can command on the social marketplace and thus failed to get a fair return on the value they bring to the relationships, or wasted investment pursuing social relationships that were higher in value than what they could realistically obtain and protect. Accordingly, Kirkpatrick and Ellis (2001) hypothesized that an important function of self-esteem was to guide individuals to approach social relationships that were of relatively high quality yet defensible given one's own social value. Their model posited that experiences of social acceptance and rejection fed into domain-specific sociometers, causing alterations in state self-esteem in the relevant social domain, which, in turn, affected aspiration levels in approaching new relationships in that domain (Zhang et al. 2015).

Conclusion

The self-esteem operates as an internal measure of one's potential for inclusion in desirable groups and relationships. It is thus essentially a meter that serves to monitor, regulate, and maintain interpersonal attachments, and it is designed to motivate behaviors to increase inclusion and forestall rejection. Self-esteem will be based on whatever criteria those important groups use to include or exclude individuals. These criteria will primarily

involve some combination of competence, likability, attractiveness, and trustworthiness (or moral character in general). State self-esteem will respond to immediate cues relevant to relational evaluation, including particular episodes of acceptance and rejection, whereas trait self-esteem will be a relatively stable appraisal of one's relational value in general (Leary and Baumeister 2000).

As a sociometer, the self-esteem system is likely to monitor the environment constantly for cues or signals that pertain to one's inclusionary status, and so automatic, preattentive processing is likely involved. Assuming that most people have some social ties most of the time, the danger of losing attachments is more urgent than the appeal of forming new ones, and so the sociometer should be especially attuned to cues that connote devaluation, rejection, exclusion, or any broadly undesirable aspect of the self. When the monitoring system detects cues suggesting that one may be rejected now or in the future, the sociometer triggers negative effect as a warning to take preventive or remedial action (Leary and Baumeister 2000).

The sociometer is tied both to specific changes in actual interpersonal relationships and to the possibility of future changes. Thus, for example, a bad test score could trigger a loss of self-esteem and resultant anxiety because it suggests a lack of competence that could make one less appealing to others (for instance, as an employee or as a provider in a close relationship). The salience, pervasiveness, and emotional power of the sociometer most likely entail it acquiring a degree of functional autonomy in the sense that people may become concerned about self-esteem without always noting the link to belongingness (Leary and Baumeister 2000).

In brief, the sociometer theory provides a broader, more parsimonious explanation of what is currently known about self-esteem.

Definition

Sociosexuality refers to individual differences in willingness to engage in casual, uncommitted sexual relationships (Simpson and Gangestad 1991).

Introduction

Two early comprehensive surveys of the sexual behaviors of North American men (Kinsey et al. 1948) and women (Kinsey et al. 1953) showed that people significantly differ on several attitudes and behaviors related to casual, uncommitted sexual relationships. To describe individual differences in sexual permissiveness and promiscuity, Kinsey and his colleagues were the first to introduce the term sociosexuality. With the exception of research on general sex drive, the majority of early research on sociosexuality was atheoretical. Other shortcomings of this research are that they did not conceptualize sociosexuality in the context of ongoing relationship and did not differentiate between sexual behaviors in committed and uncommitted relationships (Simpson et al. 2004). The scientific interest on this issue largely increased after the construction of the Sociosexual Orientation Inventory (SOI), a valid and theoretically informed measure of sociosexuality (Simpson and Gangestad 1991). Individuals with lower scores on this measure tend to have sex exclusively in emotionally close and committed relationships (restricted sociosexuality), whereas

those with higher scores tend to have sexual relationships with low commitment and investment, often after short acquaintance and with different partners (unrestricted sociosexuality).

Research consistently showed that men display more permissive sociosexual attitudes, fantasize more often about having sex with different partners, and engage in more unrestricted sexual behaviors than women. However, on almost all indicators of sociosexuality, the variability in responses within each sex is greater than that between sexes (Simpson and Gangestad 1991). Phenotypic variations in sociosexuality are substantially influenced by genes (almost 50%) and non-shared environment, and the same genes operate in males and females (Bailey et al. 2000).

Sociosexuality Measures

Among several measures of sociosexuality, the most frequently used is the Sociosexual Orientation Inventory (SOI; Simpson and Gangestad 1991). It consists of seven items that describe actual sexual behaviors (“With how many different partners have you had sex (sexual intercourse) within the past year?” and “With how many different partners have you had sex on one and only one occasion?”), anticipated (future) sexual behavior (“How many different partners do you foresee yourself having sex with during the next five years?”), frequency of cognitions about sexual behaviors (“How often do you fantasize about having sex with someone other than your current dating partner?”), and three items describing attitudes about casual sex (“Sex without love is OK”, “I can imagine myself being comfortable and enjoying ‘casual’ sex with different partners.”, and “I would have to be closely attached to someone (both emotionally and psychologically) before I could feel comfortable and fully enjoy having sex with him or her.”). Because sociosexual behaviors, attitudes, and preferences are relatively highly interdependent, they could be different manifestations of individual differences in global sociosexuality (Simpson and Gangestad 1991). Previous research shows that this measure has sound psychometric properties and is most frequently used as unidimensional, with higher scores denoting unrestricted sociosexuality

(Simpson and Gangestad 1991). However, some findings suggested that the SOI may not be unidimensional, but instead supported a two-factor structure accounting for behavioral and attitudinal sociosexuality (Webster and Bryan 2007).

In order to overcome some limitations of SOI such as its unclear structure, sometimes low internal consistency, open response items that lead to exaggerated responses, different scoring methods, and the formulation of one item that makes the SOI inappropriate for singles, the Revised Sociosexual Orientation Inventory (SOI-R) was developed (Penke and Asendorpf 2008). It consists of nine items, three for each of the three facets: past behavioral experiences referring to the number of casual and changing sex partners, the attitude toward uncommitted sex, and sociosexual desire, which represents a motivational state characterized by heightened sexual interest often associated with sexual arousal and sexual fantasies. Unrestricted sociosexual desire is conceptualized as a sexual attraction toward potential mates to whom no committed romantic relationship exists (Penke and Asendorpf 2008). Although SOI-R full-scale score and the SOI showed very similar relationships to the established correlates of sociosexuality, the results concerning three SOI-R facets show highly distinctive pattern of relationships, which may suggest that past behavioral experiences, the attitude toward uncommitted sex, and sociosexual desire are unique components of sociosexuality (Penke and Asendorpf 2008).

Empirical studies on the conditional expression of long- and short-term mating strategies showed that although men and women do not differ in their interest in long-term sexual partners, men show more interest in short-term partners than women (Buss and Schmitt 1993). Because SOI measures individual variations in the desire for short-term sexual relationships more than for long-term committed relationships, Jackson and Kirkpatrick (2007) proposed that two-dimensional model of sociosexuality that discriminates between long- and short-term sociosexual attitudes would be more appropriate than unidimensional. Accordingly, they developed a scale of human mating strategies consisting of three

factors, short-term mating orientation, long-term mating orientation, and previous sexual behavior. Their results showed that long- and short-term dimensions were largely independent and that they correlated differentially with other theoretically relevant variables (Jackson and Kirkpatrick 2007).

Theories of Sociosexuality

Several not mutually exclusive but rather complementary theoretical models are particularly useful for understanding variations in restricted versus unrestricted sociosexual orientation in men and women. One of them is life history theory (LHT) which proposes that all organisms must allocate certain amounts of their total available resources over the life span into somatic effort (e.g., growth and development of the body) and reproductive effort (e.g., mating and parenting effort) (Stearns 1992). Organisms living in harsh, unpredictable, and uncontrollable environments evolve “fast” life history strategies, allocating resources preferentially to reproductive and mating effort (r-selected organisms), whereas those living in predictable, stable, relatively safe, and controllable environments evolve “slow” life history strategies, allocating resources preferentially to somatic and parental effort (K-selected organisms) (Stearns 1992). Developmental theories based on LHT, such as psychosocial acceleration theory, propose that stressful and supportive environments influence family dynamics, especially parent-child and marital/pair-bond relations (Belsky 2012). Early experiences related to sensitivity and consistency of parenting, harsh or mild environments, and economic situation provide children with information about the kinds of environments they would most likely encounter during their lives and eventually lead to two different mating strategies, unrestricted, short-term and restricted, long-term orientation (Belsky et al. 1991). A variant of this model states that high stress and inadequate resources reflected in local mortality rates may also accelerate reproductive development (Chisholm 1996). Although many studies supported psychosocial acceleration theory, it does not adequately explain why men are more prone to short-term, unrestricted

reproductive strategies and women to long-term, restricted reproductive strategies (Simpson et al. 2004).

The explanation of different sexual reproductive strategies in men and women proposed by sexual strategies theory (SST; Buss and Schmitt 1993) is based on Trivers' (1972) parental investment theory. Because women tend to invest more in their offspring and tend to have relatively smaller number of children, they should be more selective and discriminating when choosing mates, whereas men, who have usually lower initial parental investment and may have larger numbers of offspring, should be less discriminating and more inclined to compete for mates (Trivers 1972). According to SST, during human evolution men and women have evolved different mating strategies that have helped them to solve specific adaptive problems related to reproduction. As mating strategies are context dependent, SST explains conditions within which men and women may benefit from adopting short-term (i.e., unrestricted), long-term (i.e., restricted), and a mix of these mating strategies (Buss and Schmitt 1993). Because of differences in minimal parental investment and potential number of offspring, short-term mating strategies (i.e., unrestricted sociosexuality) should be more beneficial for men than for women. Despite considerable support, SST does not fully explain why there is a greater variability in sociosexuality within both men and women than between them (Simpson et al. 2004).

According to the strategic pluralism model (SPM; Gangestad and Simpson 2000), within and between sex variations in mating strategies may be explained by principles of "good-genes" and "good-parenting" sexual selection as well as by local environmental conditions. When evaluating men as their potential mates, women evolved to make trade-offs between two dimensions: the degree of their health/viability ("good genes") and the level of their commitment/investment in the relationship and offspring ("good parenting") (Gangestad and Simpson 2000). These trade-offs depend on women's attributes such as health and physical attractiveness, as well as environmental demands such as

harshness/benignity and resourcefulness. For example, when environments are nondemanding and women have sufficient resources, their sociosexuality increases and becomes more unrestricted because they can expand additional effort to obtain access to genetically more viable men (Gangestad and Simpson 2000).

The restrictive orientation has been probably designed to facilitate paternal investment in offspring, whereas the unrestricted orientation has probably served to promote the reproductive success of offspring, particularly sons. These two global mating orientations may have evolved and been maintained through frequency-dependent selection (Gangestad and Simpson 1990). More genetically viable men may be reproductively successful without heavy investment and therefore will tend to use unrestrictive, short-term mating strategy, whereas those less viable should invest more heavily, and therefore they will use restrictive, long-term mating strategy. Although the model proposes that women's sociosexuality are more dependent on environmental demands than men's, in more demanding environments the need for biparental care increases, and therefore, restrictive, long-term mating strategy is more appropriate for both men and women. Taken together, this model postulates that men and women have a repertoire of alternative mating strategies whose adoption is under the influence of personal attributes and local environments and explains why sociosexuality is more variable within women and men than between them (Simpson et al. 2004). Research confirms that SPM is well-supported evolutionary perspective on sociosexual variation across cultures (Schmitt 2005b).

Sex ratio theory (SRT; Pedersen 1991) seeks to explain sex and cultural differences in sociosexuality. According to this theory, operational sex ratio is high when local culture includes relatively more marriage-age men than marriage-age women (usually between 15 and 49 years) and low when there are relatively more women than men (Pedersen 1991). Although there are often variations in sex ratio across cultures and historical times, women generally have a slight tendency to outnumber men mainly because of men's

greater mortality rate. Because in cultures with low sex ratio (i.e., men are more scarce than women), men can afford to be more promiscuous (i.e., show higher levels of sociosexuality), and because of mating market forces, the whole culture becomes more sociosexually unrestricted. Conversely, cultures with high sex ratios (i.e., more men than women) are associated with reduced levels of sociosexuality, because these cultures are driven more by women's than by men's sexual desires (Schmitt 2005b). Findings of two extensive cross-cultural research supported the key hypothesis of the SRT (Lippa 2009; Schmitt 2005b).

Social structural or biosocial theory (Wood and Eagly 2002) proposes that sex differences in psychological characteristics such as sociosexuality do not result from evolved psychological dispositions, but rather from social and cultural factors. According to this theory, the proximate causes of sex differences are social structure (e.g., greater male than female power, patriarchy), social roles (e.g., men as workers, women as housekeepers), and the gender ideologies behind patriarchal social structures and social roles. Because all modern societies display patriarchal social structures, although to varying degrees, they all show unidirectional sex differences in sociosexuality (Eagly and Wood 2005). Therefore, sex role socialization is sensitive to local economic and sociopolitical environments leading to sex differences in mating behaviors. In more patriarchal societies with traditional sex role ideologies, men's sociosexuality should be much higher than women's, whereas in societies with higher levels of gender equality and economic development, sex differences in sociosexuality should be weaker, which was supported by some large cross-cultural research (Lippa 2009; Schmitt 2005b).

Cross-Cultural Differences in Sociosexuality

Sex differences in sociosexuality are generally large and cross-culturally universal. Two large cross-cultural studies that included 48 (Schmitt 2005b) and 53 nations (Lippa 2009) found that in every culture, men were more unrestricted than women (average d in both studies was 0.74).

However, several mutually related factors moderate the degree of sex differences in sociosexuality. They are larger in more demanding reproductive environments (e.g., higher stress, fewer resources, higher mortality rate) and smaller in undemanding environments and cultures with higher economic development and political and gender equality (Schmitt 2005b). In cultures with more gender inequality, levels of sociosexuality in both men and women decreased although more sharply in women (Lippa 2009). Countries also differ substantially in the mean level of sociosexuality. Those with the lowest level of sociosexuality were from East and South Asia (e.g., Taiwan, Bangladesh, South Korea) and Africa (e.g., Zimbabwe, Botswana, Ethiopia), whereas those with the highest levels were from Europe (e.g., Finland, Slovenia, Lithuania), indicating that people are more sexually restricted when reproductive demands are higher and more stressful (Schmitt 2005b).

One aspect of environmental threat is a potential danger posed by infectious diseases. Namely, when pathogen transmission is highly probable, people exhibit more careful and cautious behavioral styles. Research supports the hypothesis that in regions with historically higher prevalence of infectious diseases, people show lower levels of sociosexuality. This tendency is more strongly pronounced in women than men because women face relatively higher parental investment costs than men, and, therefore, they might be more sensitive to the signals of increased costs related to unrestricted sexual behaviors (Schaller and Murray 2008). It seems that only those parasites which have the capacity for human-to-human transmission provoke threats affecting sociosexuality, whereas no such relationship was found for parasites infecting animals (Thornhill et al. 2010).

As already mentioned, sex ratio can also produce cross-cultural differences in sociosexuality. Research across 48 nations showed that sex ratios were significantly negatively related to national sociosexuality levels ($r = -0.45$). Low sex ratio (more women than men) and high sociosexuality levels were especially evident in Baltic countries, whereas high sex ratio (more men than women)

and low sociosexuality levels were evident in some Asian cultures such as Hong Kong, Bangladesh, and Taiwan (Schmitt 2005b).

Sociosexuality and Other Individual Differences

Research shows that sociosexuality is related to various psychological constructs such as personality traits and attachment styles. One of the earliest studies shows that sociosexuality was related to two higher-order personality dimensions labeled extraversion and lack of constraint and that individuals with unrestricted sociosexuality were more extraverted, aggressive, disinhibited, and more likely to lack control than those with restricted sociosexuality (Gangestad and Simpson 1990). In a large cross-cultural study encompassing 46 nations, extraversion was associated with unrestricted sociosexuality worldwide as well as across almost all 10 major world regions in both men and women (Schmitt and Shackelford 2008). Somewhat less consistent across world regions were the relations of higher agreeableness and conscientiousness with unrestricted sociosexuality. Compared to the other five-factor personality traits, neuroticism showed the lowest correlations with sociosexuality worldwide, with unrestricted sociosexuality associated with lower levels of neuroticism only in men. Openness showed positive correlations with unrestricted sociosexuality worldwide in both men and women, but these links were somewhat inconsistent, depending on sex and world region (Schmitt and Shackelford 2008). Additionally, honesty-humility factor of the HEXACO model was moderately positively related to restricted sociosexuality (Bourdage et al. 2007). Majority of the significant correlations between sociosexuality and abovementioned personality traits were low to medium. Sociosexuality was somewhat more highly related to the dark triad, a constellation of three subclinical antisocial personality traits – psychopathy, Machiavellianism, and narcissism. Psychopathy is characterized by callous affect, remorseless manipulation, and exploitativeness, narcissism by dominance, exhibitionism, exploitation, and feelings of superiority and entitlement, while Machiavellianism refers to

manipulativeness, insincerity, and callousness. All three dimensions as well as the composite of the dark triad measures showed moderate positive correlations with unrestricted sociosexuality and other indicators of short-term mating (Jonason et al. 2009). In a large cross-cultural survey across 53 nations and 11 world regions, narcissism positively correlated with self-reported unrestricted sociosexuality worldwide and across almost all major world regions. These relationships were especially pronounced with the socially maladjusted facets of narcissism, exhibitionism, exploitativeness, and entitlement (Schmitt et al. 2017). It seems that the dark triad traits and unrestricted sociosexuality are parts of fast life history strategy facilitating short-term sexual strategies. Regarding other personality traits, sensation seeking showed positive relationships with all three aspects of sociosexuality measured by SOI-R, whereas social inhibitedness (shyness) showed negative relationships with sociosexual behavior and attitude but not with sociosexual desire (Penke and Asendorpf 2008). Individuals with unrestricted sociosexuality also tend to be more impulsive and masculine and higher in self-monitoring (Simpson et al. 2004), as well as evening chronotype (Marvel-Cohen et al. 2018). As could be expected, sociosexuality was strongly related to the three scales from the Sexy Seven, instrument that measures sex-specific and evolution-relevant dimensions of individual differences (Schmitt and Buss 2000). Restricted sociosexuality was related to relationship exclusivity (low promiscuity and adultery) and sexual restraint (abstinence and prudishness), whereas unrestricted sociosexuality with erotophilic disposition (obscenity, indecency, and lust) (Bourdage et al. 2007).

Sociosexuality was also examined in relation to attachment styles. Namely, attachment theory states that early children's experiences with their primary caregivers are internalized into a framework of thoughts, feelings, and expectations regarding relationships, which continue to affect individuals' interpersonal relationships throughout their lives (Bowlby 1969/1982). Three primary attachment orientations have been determined as the most important in infant-caregiver and adult

romantic relationships: secure attachment orientation and two insecure orientations, avoidant and anxious. Securely attached individuals believe they are worthy of love and that others are trustworthy and will support them when needed. Avoidantly attached individuals believe that others are untrustworthy and experience distress when they must depend upon others, whereas anxiously attached individuals believe that they are not worthy of love and care from others and fear that others will not be supportive or will abandon them in the times of need. Research showed that secure attachment orientation was related to more restricted sociosexuality (Brennan and Shaver 1995) and that it mediated the relationship between early environments and sociosexuality in early adulthood. Namely, it seems that more predictable, stable early environments facilitate higher-quality parental care and secure attachment orientation, which results in more restricted sociosexuality in early adulthood (Szepeswol et al. 2017). On the other hand, insecure attachment, especially avoidant orientation, was related to unrestricted sociosexuality (Brennan and Shaver 1995). Dismissing attachment was cross-culturally related to unrestricted sociosexuality in most world regions and in both sexes, whereas preoccupied, fearful, and secure attachment generally showed low and inconsistent relations with sociosexuality across gender and world regions (Schmitt 2005a). However, many relationships obtained between attachment and sociosexuality were relatively small and most frequently found in Westernized cultures (Schmitt and Jonason 2015).

To summarize, individuals with unrestricted sociosexuality tend to be more extraverted and open to experience, less agreeable and conscientious, more aggressive, disinhibited, impulsive and masculine, as well as higher sensation-seekers. They also tend to be higher on all dark triad traits and personality attributes related to erotophilia, more avoidantly attached, and evening chronotype. On the other hand, sociosexually restricted individuals could be described as more introverted, agreeable, conscientious, inhibited, honest and humble, as well as less aggressive, impulsive, and less open to

experience. They also tend to be lower on all dark triad traits and higher on personality attributes related to relationship exclusivity and sexual restraint as well as more securely attached and morning chronotype. Personality characteristics related to unrestricted sociosexuality are likely to facilitate successful pursuit of short-term mating strategies, while those related to restricted sociosexuality may be helpful in effective enactment of long-term mating strategies (Simpson et al. 2004).

Sociosexuality and Mating Behavior

Global sociosexuality as well as its components show moderate to strong associations with a wide range of mating behaviors. It was found that persons with restricted sociosexuality have a tendency to be more attracted by potential partners' attributes such as loyalty, faithfulness, and responsibility, as well as personal compatibility with them, characteristics that usually facilitate and help to maintain stable, committed, and long-term relationships. Those with unrestricted sociosexuality tend to be more attracted by physical/sexual appeal and social visibility of their potential partners, which are important features for initiating and developing short-term relationships (Simpson et al. 2004). Sexually unrestricted persons seem to be especially sensitive to physical characteristics that signal reproductive value of a potential partner. For example, unrestricted women prefer men with more masculine bodies (Provost et al. 2006), and sexually unrestricted men prefer women with low waist-to-hip ratio, an indicator of women's fertility (Price et al. 2013).

It should be noted that people could validly assess sociosexuality of previously unacquainted individuals on the bases of their nonverbal behavior and that men assess sociosexuality more accurately in women than women do in men. Unrestricted men are more likely to smile, display head cants, flirtatious glances, and are perceived as socially engaging and dominant, whereas unrestricted women are more likely to lean forward and cant their heads (Simpson et al. 1993). Relatedly, unrestricted people were more attracted to potential dating partners who display flirtatious

glances, intermittent gaze aversions, and head cants (Simpson et al. 2004).

Unrestricted persons are more likely to get involved in extra-pair sexual relationships and exhibit a pattern of sexually assertive behaviors such as more frequent flirting and engaging in socially dominant behaviors (e.g., maintaining eye contact and close physical proximity during social interactions), along with chronic, heightened responsiveness to situational sexual cues (Penke and Asendorpf 2008; Simpson et al. 2004). In both sexes, unrestricted sociosexuality was linked to different mate poaching experiences such as mate poaching attempts, being the target of mate poaching attempts, and being successfully poached (Grundler et al. 2013). Therefore, positive links between unrestricted sociosexuality, especially perceived sociosexuality of one's partner and mate retention behaviors, are not unexpected (Kardum et al. 2006). Additionally, unrestricted sociosexuality, especially sociosexual desire, was negatively related to relationship quality, commitment, investment, and fidelity, and it predicted relationship dissolution and sexual involvement with new partners (Penke and Asendorpf 2008). However, it seems that if unrestricted persons have romantic relationships in which they agree with partners about the possibility to satisfy their need for sex with other people, their relationship quality will not be negatively affected (Rodrigues et al. 2016). It should be mentioned that many mating behaviors could be related to some specific components of sociosexuality. For example, sociosexual attitude was the only component that did not contribute to the prediction of future sexual behavior and relationship outcomes (Penke and Asendorpf 2008).

Sociosexuality is also associated with not so obvious although theoretically meaningful outcomes. For example, because men tend to exhibit greater variability in their total number of offspring than women do, SPM predicts that genetically predisposed unrestricted women typically should have benefited from having relatively more sons ("sexy son" hypothesis), while genetically predisposed restricted ones should have benefited from having relatively more daughters, which was supported in three studies (Gangestad and Simpson 1990).

Conclusion

Over the last several decades, the study of individual differences in sociosexuality as well as its underlying mechanisms greatly advanced our understanding of the important aspects of interpersonal relationships, i.e., sex and sexuality. Sociosexuality is especially relevant in explaining gender and cross-cultural differences in sexuality and their implications, as well as how social and physical environmental factors affect reproductive behavior. These advances were possible because the concept of sociosexuality is theoretically well-grounded and has clear and valid operationalizations. The abundance of studies embedded sociosexuality within a nomological network of relations with a wide range of other individual difference variables and consequential mating behavior, showing fundamental differences between short- and long-term mating strategies.

Definition

Men and women differ in terms of their sociosexuality, or evolved preferences for whether and how soon to have sexual relations. Reflecting these differences, the sexes often come into sexual conflict.

Introduction

Sociosexual orientation, or sociosexuality, is a construct reflecting an individual's tendency to engage in casual, uncommitted sexual relationships. It is commonly measured by the Sociosexual Orientation Inventory (SOI) (Simpson and Gangestad 1991), which measures both behavioral elements – past number of partners, predicted number of future partners, number of one-night stands, frequency of sexual fantasies – as well as attitudes toward engaging in casual, uncommitted sex. Individuals with a restricted sociosexual orientation are more likely to insist on commitment and closeness in a relationship before engaging in sex and to pursue a long-term mating strategy, while those with an unrestricted sociosexual orientation are more likely to be comfortable engaging in sex without commitment or closeness and to pursue a short-term mating strategy.

Sex Differences in Sociosexuality

On average, men have evolved to have a more unrestricted sociosexual orientation than women. This difference can be traced back to Trivers' (1972) theory of parental investment and sexual selection. That is, men are biologically required to invest much less than women in their offspring. Men only need to contribute a few sex cells and a few minutes of their time, while women must go through 9 months of pregnancy before the offspring is born and, in natural settings, several years of post-birth lactation. Because of these key differences, men have more to gain than women – in terms of reproductive fitness – from having frequent sex with several partners; such behavior leads to a direct increase in the number of offspring produced while incurring relatively little cost for men, but not women. As such, men have evolved to have a greater desire for casual sex than women. In contrast, ancestral women would have faced a high cost if offspring were produced as a result of uncommitted sex as they would have to go through a long period of gestation and ensure the survival of the offspring without any help from a reliable and resourceful father. This high cost of casual, uncommitted sex has resulted in women evolving a more restricted sociosexual orientation as compared to men.

Consistent with the theory, a worldwide study spanning 48 nations revealed that sex differences in sociosexuality in the predicted direction were large and were universal across cultures (Schmitt 2005). Due to their relatively unrestricted sociosexuality, men prefer to engage in sex sooner than women and pursue it more persistently and aggressively. Indeed, men are more willing to have sex than women at every time interval of knowing a potential mate up to 5 years (Buss and Schmitt 1993). Only at 5 years of acquaintanceship are women, who require investment and commitment from their partner, equally likely interested in engaging in sex. The result of these opposing sexual strategies and sex differences in sociosexuality lead to much potential sexual conflict between men and women, including conflict over the occurrence and timing of sex and much of the sexual aggression that occurs.

Conflict About the Occurrence and Timing of Sex

A major source of sexual conflict concerns decisions over *whether* sex will occur and *when* it will occur. As described above, men, on average, have evolved to desire to have sex with more partners sooner and without significant prior investment, while women, on average, have evolved to prefer less partners and to grant sexual access upon having obtained proof of resources and commitment. These different and somewhat opposing strategies are associated with different cognitive biases and deceptive tactics on the part of both sexes (Haselton and Buss 2000).

Regarding biases, because individuals are typically uncertain about the feelings and intentions of potential mates, they have to make judgments one way or the other. Regarding perceptions of sexual interest, there are two types of errors that can be made: falsely inferring sexual interest when there is none and failing to detect sexual interest when it exists. According to error management theory (Haselton and Buss 2000), the reproductive costs of these two errors are unlikely to be identical. Therefore, selection pressures would have produced cognitive biases that aim to avoid incurring the more costly error. Which is the more costly error differs for men and women. For men, missing an actual sexual opportunity (and thus, missing an opportunity to increase reproductive fitness) is generally costlier than pursuing a nonexistent sexual opportunity (which may waste a degree of time and energy). Hence, men may have evolved to overestimate the amount of sexual interest a woman has in them. As a result of this bias, men will miss less sexual opportunities that exist but will also make a number of unwanted sexual advances toward women who are not actually interested. Consistent with this reasoning, men perceive more sexual intent in opposite-sex interactions than women do, and women more than men experience their own friendliness as being misperceived as a sexual invitation (e.g., Abbey 1982). Indeed, a lot of unwanted male sexual attention occurs in the modern workplace, resulting in the filing of sexual harassment claims from mostly women.

An interesting real-world example of this occurred when a supermarket chain instructed their employees to smile at and make eye contact and pleasant conversation with their customers. Female employees became the target of unwanted sexual comments, come-ons, and pursuits because male (but not female) customers had perceived the friendly behavior as signaling sexual interest. It should be noted that it is not entirely clear whether, in this and other instances of conflict, men are overperceiving sexual interest or whether women are deceiving. In this case, the employees were not actually behaving naturally but in accordance to company instructions. Furthermore, if the employees' behaviors had been freely chosen rather than instructed by the company, the behaviors (which clearly stand out from the usual impersonal and less friendly service provided by most cashiers) could arguably indicate a level of potential interest or an attempt to feign sexual interest. If so, then rather than simply concluding that men are overperceiving, it may be more accurate to say that men were responding to cues that would normally be put forth when women actually want to signal sexual interest. These competing possibilities have yet to be thoroughly examined. At any rate, the sex difference is clear: male but not female customers' behavior indicated perceptions of sexual interest.

In contrast, women face a different kind of error asymmetry: consenting to sex without commitment tends to be a more costly error for women than waiting a longer time for sexual relations to commence, thus making women more susceptible to the commitment skepticism bias, where they tend to underestimate a man's actual level of commitment early in courtship (Haselton and Buss 2000). Such underestimation tends to encourage further escalation of commitment from male partners before sex occurs.

In conjunction with these cognitive biases, the sexes also engage in the use of deceptive tactics to further their own respective strategies. For instance, men often exaggerate the depth of their feelings to indicate commitment and thus, to speed up the occurrence of sex. A study of college men and women found that 71% of men reported having ever exaggerated their feelings to get sex,

while only 39% of women had done so. On the other hand, more women than men admit manipulating perceived sexual access. That is, women more than men report using their sexuality, such as smiling and flirting, to get favors from the opposite sex even though they have no sexual interest. Moreover, more women than men report engaging in sexual withholding, where they delay the occurrence of sex in order to increase men's investment and commitment.

Sexual Aggression

Although some conflicts are benign, consisting of annoyances and temporary misunderstandings, the opposing sexual strategies of men and women as a result of their differing sociosexual orientations can sometimes result in more serious forms of conflict, including sexual aggression and rape. Because of men's evolved desire to have sex sooner and without the need for significant investment and women's evolved reluctance and need for commitment, men may sometimes resort to forcing their sexual interest on reluctant women. These acts of sexual aggression can be directed towards single women, or a man's current partner. Victims are disproportionately concentrated among young and physically attractive women, indicating that male sexual aggression is primarily aimed at generating reproductive fitness. Women are also more likely to experience greater distress from sexual aggression than men, citing it as more upsetting than verbal or nonsexual physical abuse (Buss 1989). The conflict of sexual aggression is made even worse by the fact that men underestimate how upsetting sexually aggressive acts are to women, which may incline some men to engage in such behaviors more often.

Rape occurs when sexual aggression involves forced sexual intercourse. A controversial issue in evolutionary psychology is whether rape is an adaptation designed to obtain sexual access when consensual opportunities are lacking (Thornhill and Palmer 2000). In one study, 35% of men indicated that they would consider forcing sex on a woman against her will if there was no chance of getting caught. Victims of rape also tend

to be young and fertile women, and the pregnancy rate associated with rape is higher than the rate for consensual sex. Although these findings support the perspective that rape is an adaptation, they do not sufficiently distinguish from the alternative perspective that rape is a by-product of other evolved mechanisms, such as a desire for sexual variety and greater physical aggression. Regardless of which perspective is more accurate, rape has occurred throughout human history and as such, women have also been hypothesized to have evolved anti-rape adaptations, such as making alliances with male friends for protection, avoiding risky activities during ovulation, and experiencing psychological pain from rape to avoid it in future. However, research on women's evolved defenses against rape is still in its infancy and more work is needed in this area.

Individual Differences

Although men have tended to evolve different sociosexualities than women have, not all men are higher on sociosexuality than all women. There are important within-sex differences. For example, asymmetry is negatively correlated with sociosexuality (Gangestad and Simpson 2000). For men who are lacking in attributes that women find attractive in short-term mates, such as facial symmetry, the costs of pursuing a short-term mating strategy are likely to outweigh the benefits. It would be more beneficial for these men to embrace a more restricted sociosexual orientation and thus, invest heavily in a long-term mating strategy and a single mate's offspring. Such within-sex differences in sociosexuality also lead to within-sex differences in some areas of sexual conflict. For example, men who are more inclined to pursue a short-term mating strategy are more susceptible to the sexual overperception bias (Lenton et al. 2007) and are therefore more likely to get involved in conflicts about sexual access and whether sex will occur.

Furthermore, the magnitude of these sex differences tends to vary across cultures (Schmitt 2005). In cultures where the environment is more demanding (e.g., fewer resources, higher

mortality), sex differences in sociosexuality have been found to be larger, presumably because women are more monogamous in response to the environmental demands for better offspring care. Men, on the other hand, may still benefit from short-term mating, regardless of environmental influences. Cultures with more traditional sex role ideologies may also have larger sex differences in sociosexuality. Women are more constrained in these societies economically, politically, and reproductively, which promotes a more restricted sociosexual orientation as compared to men.

Conclusion

This entry has described the link between sex differences in sociosexual orientation – the degree to which people seek sexual relations without commitment – and key sexual conflict dynamics. Future research, guided by an evolutionary perspective on sex and within-sex differences in sociosexuality and sexual conflicts, is needed to shed further light on the dynamics of human mating as well as provide insights on how to prevent sexual conflict.

Solution to Paternity Uncertainty

Rebecca L. Burch

Anti-cuckoldry tactics; Paternal assurance tactics

Definition

Due to internal fertilization, human males cannot be sure that they are investing in their own biological children. As a result, men have developed solutions to this issue: anti-cuckoldry, or paternal assurance, tactics.

Introduction

Because of internal fertilization, human males cannot be sure that the children they invest in are biologically related to them. The threat of cuckoldry was examined thoroughly by Anderson (2006); the incidence of nonpaternity rates from paternity testing laboratories (involving samples that in some cases were in the thousands) ranged from 14.3% to 55.6%. Anderson partitioned the incidence of nonpaternity into males with high paternity confidence (i.e., males who had no reason to question their paternity) and those with low paternity confidence. Among those with high paternity confidence, the incidence of nonpaternity was approximately 2%. For those with low paternity confidence, however, the incidence of nonpaternity was 30%. First, this shows that cuckoldry can be a significant factor in male reproduction. Second, this shows that men question their paternity and attempt to determine paternity to make investment decisions. They also engage in various tactics to increase their paternity confidence.

Paternal Assurance Tactics

Gallup and Burch (2006) created a model to describe the motivations for, and ways in which, men attempt to solve the problem of paternal uncertainty. The model outlines four categories of tactics: insemination prevention, counter insemination, pregnancy termination, and postpartum investment. Each of these categories of strategies is implemented by men in sequence and according to context.

Insemination Prevention

The first and most obvious paternal assurance tactics are those that involve *insemination prevention strategies*. Common tactics for insemination prevention involve keeping women away from other men, particularly if it is unmonitored. This can begin even as women are still girls as this will not only affect their marriageability and their family's reputation in several cultures. A woman who is unfaithful to her husband puts her children's livelihoods in danger, but also may be perceived to be possessing a heritable trait, leaving her mother's fidelity, and therefore her father's paternity, in doubt. Because of this, parents may be just as invested in perceived female purity as prospective mates (Burch 2019, *in press*).

To insure that the female partner has previously avoided men and is not predisposed to seek them out, men often insist on virginity or little sexual experience (Espin 2018; Bekker et al. 1996). This idea, that low promiscuity becomes low infidelity after marriage, was supported by Essock-Vitale and McGuire (1985) who found that among adult women, promiscuity prior to marriage was also a predictor of infidelity once women were married. Other attempts to prevent infidelity or insemination by other males include physically restricting female sexuality through mechanical means like chastity belts, or surgical means like female genital mutilation and infibulation (see Daly et al. 1982, for review). It is important to note that these strategies are implemented as girls grow into sexual maturity, ensuring their virginity for future husbands, and used by those husbands throughout their marriages.

The most widely researched insemination prevention tactic is mate guarding, motivated by male sexual jealousy (Daly and Wilson 1988). What is sexual jealousy other than the fear of cuckoldry? Sexual jealousy can manifest itself in indirect monitoring of the female partner (checking mileage on the family car, checking phones and other devices, asking others to monitor or report on her behavior), limiting the number of places the female is allowed to go alone (or "unsupervised"), restricting her resources so

she cannot venture out, separating her from family and friends, or creating conflict when she violates these restrictions (see Buss 2002 for review). Jealousy can (and often does) escalate into severe isolation and abuse. Sexual jealousy has been described as one of the most frequent motivators of domestic assault (Wilson and Daly 1996).

Counter Insemination Strategies

However, if these mechanisms fail and insemination of the female occurs as a consequence of extrapair copulation, *counter insemination strategies*, such as sperm competition (Baker and Bellis 1995; Birkhead 2000) and semen displacement (Gallup et al. 2003) are then implemented.

Sperm competition refers to the competition between the ejaculates of two different men when a woman mates with more than one man within a small window (given the lifespan of sperm, this is typically less than 48 h but can extend days) (Baker and Bellis 1995). Baker and Bellis (1993) surveyed over three thousand women through a British magazine and found that one-half of women had double mated within their first 500 copulations, and over 80% had double mated by the time they had experienced 3000 copulations. Approximately 30% of women reported having been inseminated by two males within 24 h on one or more occasions.

If and when double mating occurs, males have developed strategies to compete against rival males. First of all, jealous men are more likely to insist on frequent sex with their partners, essentially putting their sperm into competition with suspected rivals (Shackelford et al. 2007). Men have also insisted or even forced their partners into sex when they have suspected infidelity (Goetz and Shackelford 2006). In addition, there is evidence that not only do men make sure their sperm are in competition when they suspect infidelity but they also put

more sperm in competition. Kilgallon and Simmons (2005) found that when men were shown pictures designed to simulate sperm competition, such as sexually explicit images of two men and a woman, they had significantly higher proportions of mobile sperm in their ejaculates. Men who masturbate while watching pornography of other men having sex with women produce greater volumes of seminal plasma, higher sperm counts, higher percentages of morphologically normal sperm, and greater sperm motility (Yamamoto et al. 2000).

Another counter insemination strategy would be to remove the sperm of rival males from the female reproductive tract. As odd as this sounds, semen displacement is an evolved feature of human penile morphology, where semen from rival males is displaced from the cervical area of the vagina by the coronal ridge of the glans of the penis through thrusting during sex. After displacing the rival semen, the resident male can then ejaculate at the cervical end of his partner's vagina. If semen displacement was a mechanism to prevent insemination by rival males, thrusting (and therefore displacement) would be increased in situations where men suspected infidelity. Gallup et al. (2003) found that following allegations of female infidelity or periods of separation, the majority of males and females reported increase in both the depth and vigor of thrusting. This would enhance the magnitude of semen displacement.

Pregnancy Termination Strategies

If a man suspects infidelity and his female partner becomes pregnant, he may suspect that the child is not his. This may be evidence that his insemination prevention and counter insemination strategies have failed, and the pregnancy would be potential cuckoldry. At this stage, men may employ *pregnancy termination strategies*. Pregnancy termination can occur through chemical (semen composition) or physical (abuse) means.

It is important to note that suspicions of cuckoldry may not be founded, but this does diminish male behavior. Just as with sexual jealousy and paternal resemblance (see below), it is the perception that motivates the tactics. For example, Campbell et al. (1992) found that regardless of actual paternity, men still suspected their partners had been unfaithful, and this resulted in physical abuse during their pregnancies. Likewise, Burch and Gallup (2004) found that among men convicted of domestic violence, the frequency and severity of abuse men doubled when the woman was pregnant. Men reported that sexual jealousy was the prime motivator of violent incidents. The men who abused their pregnant partners reported greater sexual jealousy and questioned the paternity of the unborn child. Physical abuse directed toward their pregnant partner's abdomen was common, making the purpose of the abuse clear.

Interestingly pregnancy termination attempts can also be chemical in nature. For example, it appears that repeated exposure to the biological father's semen may be a factor in pregnancy maintenance. Women who have limited exposure to the biological father's semen are at an elevated risk for preeclampsia (Robertson et al. 2003), a contributing factor to maternal mortality and a major cause of perinatal morbidity and mortality (Klonoff-Cohen et al. 1989). Treating women who suffer recurrent miscarriages with seminal plasma also improves pregnancy success (Stern and Coulam 1993), and the risk of preeclampsia is reduced by repeated semen exposure over time (Klonoff-Cohen et al. 1989). Dekker et al. (1998) identified changes in "paternity" as playing a role in preeclampsia. Additionally, live birth rates in couples undergoing in vitro fertilization are significantly improved when they engage in intercourse prior to embryo transfer (Tremellen et al. 2000). In other words, pregnancies from a resident male are more successful and seminal plasma is a clear mechanism.

As would be expected following this model, men who attempt to prevent cuckoldry and

suspect that a pregnancy may not be theirs would likewise suspect children in the family may not be related to them and may in fact be cuckoldry in action. As a way to solve this problem of paternal uncertainty, males will look for cues to paternity and engage in postpartum investment strategies, detecting cues to certainty and making investments in children according to those cues.

Postpartum Investment Strategies

Just as during pregnancy, men may not believe the children in the home are theirs. According to the model, men unsure of their paternity may see children as evidence that insemination prevention strategies, counter insemination strategies, and pregnancy termination strategies have all failed. It is also important to note that men may be engaging in postpartum investment strategies with existing children, while engaging in any of the other strategies with the female partner at the same time. For example, he may be mate guarding his partner but also using cues from his children to make decisions about his children. He may also use cues from his children to make decisions about this partner, and vice versa (see below). A father may also have a higher paternity confidence with one child and lower with another, based on previous circumstances or partner behavior. But most of all, men will look to cues in the children themselves to determine investment, investing the most in those that provided the greatest paternal certainty. Paternal investment could range from significant investment, to indifference, neglect, abuse, abandonment, and even infanticide (Daly and Wilson 1996).

Using paternal resemblance as a cue and making investment decisions based on it is a significant postpartum investment strategy, an attempt to solve the problem of paternal uncertainty. Burch and Gallup (2000) asked abusive men to report how much they thought each child in their home resembled them, then asked questions regarding

child and partner investment. The more the abusive men thought a given child resembled them, the better they rated their relationship, and the better the child was treated. The more the men thought their children resembled them, the less violence and abuse they inflicted on their female partners as well, showing that these strategies and cues are interrelated.

Platak et al. (2002) created a more controlled study, but examining the reactions of male and female college students to morphed images of children's faces. The children's pictures were digitally morphed with either images of the subjects themselves or one of four other people of the same sex, then subjects were presented with hypothetical parental investment scenarios and asked to choose which child's picture they would invest in. Males chose their own morphed picture more often than females in almost every positive investment category and less often in almost every negative investment category. Platak et al. (2003) investigated whether this effect was caused by a greater ability in males to detect resemblance. There is no sex difference in the ability to detect resemblance, but males were far more likely than females to make investment decisions based on resemblance. Thus the literature overwhelmingly implicates a male specific effect of resemblance in child investment. Indeed, males who committed infanticide cited a lack of resemblance implying non-paternity as a reason (Daly and Wilson 1984). Resemblance has been implicated in the father/child relationship (Apicella and Marlowe 2004), with perceived child resemblance valued more highly by men (Volk and Quinsey 2002).

As evidence that these strategies are attempted solutions to paternal uncertainty, these male behaviors shift dramatically with knowledge of paternity. Burch and Gallup (2000) found that the presence of children that were explicitly *unrelated* to the male (e.g., children from a female's previous relationship or a stepchild) greatly increased the amount of violence in the home. In this situation, paternity (or nonpaternity in this case) is certain. Daly and Wilson assembled

cross cultural evidence showing that non-biological parents are as much as 100 times more likely to kill their children than biological parents (Daly and Wilson 1985, 1996, 1998).

Conclusion

Paternal uncertainty has an enormous and varied impact on male behavior and investment. This is just a brief overview of these paternal assurance strategies and how each has evolved to solve the problem of paternal uncertainty (each strategy can be, and is, reviewed in more detail, particularly ► [Sexual Jealousy](#), ► [Sperm Competition Theory](#), and ► [Resemblance](#)). Men use these strategies according to level of uncertainty, suspicion of infidelity, and other contextual factors (for example, a man may choose to not invest in any of his children, regardless of resemblance, and focus reproductive efforts on insemination and not child investment) as solutions to paternal uncertainty, attempting to maximize fitness by making the correct reproductive decisions.

Definition

Representations of discrete and continuous quantities.

Introduction

How many cookies are on that plate? How big are they? How many seconds will it take to devour them? From infancy to adulthood and across human and nonhuman species, the ability to quantify space, time, and number has been shown to be critical for basic processes including foraging, language acquisition, and basic learning, but also for the acquisition of more complex processing such as formal mathematics. Because representations of time, space, and number are not tied to any one sensory modality (e.g., different durations, set sizes, or dimensions of space can be seen, heard, or felt), these quantities are uniquely abstract in nature and omnipresent throughout our daily experiences. While the ability to represent exact quantities symbolically (i.e., denoting quantity information using language (*four seconds*) or Arabic numerals (25.8)) does not occur until later in human life, the ability to represent these abstract quantities in an approximate nonsymbolic manner has been demonstrated in preverbal infants (e.g., Lourenco and Longo 2010) and in a variety of nonverbal nonhuman species (see Gallistel 1990), providing substantial evidence that these representations are not linguistically dependent. This entry highlights the key features of space, time, and number

representation, considering current proposals regarding the format of these representations.

Key Features of Space, Time, and Number

Adherence to Weber's Law

It has long been noted that temporal, numerical, and spatial quantity (i.e., length or area) discriminations adhere to Weber's law, such that the speed and/or accuracy of the discriminability of two values, be they durations, areas, or numbers, is dependent upon their ratio (e.g., Stevens 1957). For example, the ease with which a set of 10 items is discriminated from a set of 20 is comparable to the ease with which a set of 40 items is discriminated from a set of 80, since both comparisons involve a 1:2 ratio change. This ratio dependence of quantity discriminations has been demonstrated across a variety of nonhuman species (see Gallistel 1990) and across human development (see Feigenson 2005). To account for the Weber-like characteristic of quantity discriminations, it has been proposed that spatial, temporal, and numerical quantities (both symbolic and nonsymbolic) are represented via a noisy (i.e., imprecise) analog mental magnitude system (Meck and Church 1983). In the numerical cognition literature, this system is frequently referred to as the approximate number system or ANS (Feigenson et al. 2013).

Increasing Precision Throughout Development

Quantity discriminations obey Weber's law throughout development; however, evidence also reveals that the precision of these discriminations increases with age (e.g., Odic et al. 2013; Droit-Volet et al. 2008). In infancy, a comparable developmental trajectory for spatial, temporal, and numerical discriminations has been found, with 6-month-old infants consistently discriminating changes involving a 1:2 ratio change, but not a 2:3 ratio change, and 10-month-olds successfully discriminating a 2:3 but not a 3:4 ratio change for time and number (see Feigenson 2005). However, in older children, the ease with which these

quantities can be discriminated differs, with evidence suggesting that area acuity is higher than that of numerical acuity (Odic et al. 2013), with timing acuity being even lower (Droit-Volet et al. 2008). Given links between representational acuity and formal math abilities, it is important to understand the source of this developmental change, yet more work is needed.

Neural Activation

While some evidence demonstrates overlapping intraparietal sulcus (IPS) activation during estimation of time, space, and number (e.g., Dormal and Pesenti 2012), other studies provide evidence for distinct neural activations across these quantities (e.g., Mattell and Meck 2004). An overwhelming amount of evidence suggests that the IPS is relevant for numerical and spatial tasks. For example, when participants are asked to judge the numerosness of a display and/or the length of a line, then activation in the IPS occurs (Dormal and Pesenti 2012). It is not clear whether the IPS is implicated in timing though. In fact, substantial evidence from drug, lesion, clinical, and imaging studies in both rodents and humans points to the basal ganglia as the center of interval timing (see Mattell and Meck 2004), suggesting a neural dissociation between space, time, and number.

Despite evidence suggesting distinct neural activation patterns across representations of space, time, and number, there are striking comorbidities of temporal, spatial, and numerical deficits found in many disorders. For example, patients with genetic disorders such as Turner syndrome, fragile X, and chromosome 22q11.2 deletion syndrome also experience deficits in mathematical, spatial, and temporal processing (Vicario et al. 2013). Individuals with left neglect, a condition in which individuals struggle attending to or experience a lack of awareness of space, also exhibit difficulties accurately estimating time and show disrupted numerical processing (see Dormal and Pesenti 2012). Together, these consistencies across clinical populations hint at some degree of neural overlap.

Representing Small Versus Large Values: Two Distinct Systems

Substantial evidence points to breaks in the mental timeline and the mental number line, such that representations of smaller values may be represented in a distinctly different fashion than those of larger values (see Buhusi and Cordes 2011). Distinct neural activation patterns and different behavioral patterns when timing short (subsecond; i.e., <1 s) compared to long (suprasecond) durations in both animals and humans have suggested the presence of two separate timing systems (Gooch et al. 2011). Relatedly, there is also evidence that number is represented via two distinct systems: one for small sets (less than 4 or 5) and another for large sets (>4 or 5). Separate neurological structures have been implicated during estimation of small relative to large sets (Ansari et al. 2006). Most strikingly, substantial behavioral data reveal remarkable dissociations when young infants discriminate small from large sets (see Posid and Cordes 2015). There is no evidence to date, however, in support of distinct systems for representing small and large spatial extent.

Cross-Domain Interference

Other work has explored how these quantity representations may be altered by the presence of other quantitative information (a question of the relative dependence of quantity representation; see Dormal and Pesenti 2013). Results of these studies have generally revealed adult abilities to track spatial, temporal, or numerical information to be altered by the presence of other numerical and spatial information, but not temporal information (e.g., Dormal et al. 2006; Merritt et al. 2010). For example, Dormal and Pesenti (2013) designed a three-dimensional Stroop task in which participants were presented with two arrays of dots, which differed in number of dots, spatial extent (length of the array), and duration of presentation. Participants were either asked to judge (1) which array was more numerous, (2) which was physically longer, or (3) which was presented for the longer duration (between subjects). Results revealed that both the relative numerosness and

length of the arrays significantly interfered with temporal judgments. Temporal cues, however, did not significantly impact either numerosity or length judgments (Dormal and Pesenti 2013).

Cross-Domain Transfer

A number of studies have reported spontaneous cross-domain transfer, in which animals, preverbal infants, and adults have spontaneously applied rules learned in one quantitative domain to a novel quantity. Cross-domain transfer has been shown as early as infancy (e.g., Lourenco and Longo 2010) and across nonhuman species (Meck and Church 1983). The first evidence of cross-domain transfer was demonstrated when rats were trained to discriminate between two distinct durations (2 s vs. 8 s). During the test trials, rats were presented with ambiguous stimuli that were always 4 s long (the geometric mean of the two trained standards), but varied in number. The rats spontaneously responded on the task as if they had originally been trained with numerical stimuli, classifying stimuli involving larger numbers in the same way in which they originally classified longer durations, producing overlapping response distributions for temporal and numerical judgments (Meck and Church 1983). More recent studies with human infants have also revealed the spontaneous generalization of a pattern or rule in one domain (i.e., increasing numerical values) to another domain (i.e., increasing line lengths). For example, when infants were shown that larger objects had certain features (i.e., objects were black with stripes) relative to smaller objects (i.e., objects were white with dots), infants expected this rule to generalize to numerosity and duration (Lourenco and Longo 2010). It has been argued that these findings suggest that infants treat time, space, and number as falling along a single dimension.

Other work on cross-domain mappings has pointed to a privileged relationship between space and number. Some work suggests that number may be inherently mapped in an increasing order from left to right. The Spatial Numerical Association of Responses Codes (SNARC) effect, a phenomenon in which smaller numerical values

are associated with the left and larger numerical values are associated with the right, has been demonstrated in children and adults (Dehaene et al. 1993). For example, when asked to judge the parity of a digit (odd/even), participants are faster to respond with the left hand when the numerical value of the digit is small compared to when it is large and faster to respond with the right hand when the numerical value of the digit is large compared to when it is small (Dehaene et al. 1993). Although this SNARC effect seems to track with the direction of reading in the culture, such that individuals in cultures that read from right to left exhibit a reverse SNARC effect (Dehaene et al. 1993), more recent work has suggested that the SNARC effect may not be culturally dependent and instead reflect evolutionarily derived natural proclivities. For example, Rugani et al. (2015) trained chicks to retrieve food from behind a panel depicting an array of dots, always with the same standard number (5). Then, during test, the chicks were presented with two side-by-side panels, both displaying the same set size (i.e., 10 dots). When the number of dots on the card was larger than the trained standard, chicks were significantly more likely to retrieve food from behind the right panel. On the other hand, when the number of dots on the card was smaller than the trained standard, chicks were more likely to go to the left panel. This robust pattern provides some of the first evidence to suggest that number, even in nonhuman species, may be represented in a left-to-right orientation in the mind.

Basic Quantitative Processing and Academic Achievement

A significant amount of work has shown a relationship between our approximate sense of number and formal math abilities (for a review, see: Feigenson et al. 2013, but also see: Gilmore et al. 2013). The predictive relationship between numerical acuity and math achievement appears to be bidirectional, with preschoolers' numerical acuity predicting math abilities at age 6 and formal math abilities in kindergarten predicting numerical acuity at 14 years of age (see Feigenson

et al. 2013). While most of this work is correlational, some training studies have pointed to a causal relationship between our approximate number system and formal math abilities (e.g., Wang et al. 2016).

The strength of the relationship between numerical acuity and math achievement, relative to that of other numerical abilities and math abilities, has been called into question, however (e.g., Gilmore et al 2013; Skagerlund and Traff 2015). For example, Skagerlund and Traff (2015) investigated basic quantity processing and formal math abilities in 8–10-year-olds and found that symbolic number comparison, but *not* nonsymbolic numerical discrimination, predicted formal math abilities. The authors suggest that once children become comfortable with the symbolic nature of mathematics, the importance of the approximate number sense becomes less indicative of formal math ability.

Spatial abilities, including mental rotation and quantitative spatial tasks, are also predictive of formal math abilities (for a review: Mix and Cheng 2012). In one study, adults completed an approximate number judgment task, an approximate surface area judgment task, and a set of standardized math assessments. Results revealed that adults' abilities to discriminate both number and surface area were correlated with formal math abilities (Lourenco et al. 2012). Other work ties spatial processing specifically to mathematical equation solving (Skagerlund and Traff 2015).

Most recently, timing abilities have also been linked to formal math achievement (e.g., Skagerlund and Traff 2015). For example, temporal discrimination abilities have been found to predict calculation skills in children (Skagerlund and Traff 2015). However, the link between nonsymbolic magnitude processing and mathematical abilities is not robust (see Agrillo et al. 2013), and thus more work is needed to fully understand the relationship between basic quantitative processing – including nonsymbolic temporal, spatial, and numerical processing – and formal mathematics.

Does a Common Magnitude System Exist?

Some researchers have suggested that a single common cognitive system may be responsible

for processing space, time, and number (e.g., Meck and Church 1983; Walsh 2003), in which spatial, temporal, and numeric magnitudes may be processed identically within a single neural locus. Proponents of a common magnitude system have cited identical behavioral signatures (i.e., adherence to Weber's law), common developmental trajectories, some evidence of neural overlap, cross-domain transfer, and quantity interference as support in favor of a single quantity processing system (e.g., Walsh 2003).

Despite the remarkable similarities across spatial, temporal, and numerical processing identified, other researchers have identified a number of inconsistencies calling into question the idea of a common magnitude system. For example, despite seemingly similar discrimination patterns across infancy, other work has revealed dissociations between temporal, numerical, and spatial discrimination abilities across individuals (e.g., Odic et al. 2013; Young and Cordes 2013). Moreover, the relatively limited evidence in support of neurobiological overlap across representations of quantity, striking dissociations across temporal and numerical biases (Young and Cordes 2013), and findings suggesting that spatial, temporal, and numerical abilities may each uniquely predict (or not) distinct aspects of formal math abilities (Agrillo et al. 2013; Skagerlund and Traff 2015), have caused some to rethink claims of a common system. As such, it has been posited that space, time, and number may instead be represented by three distinct, yet similar, cognitive systems.

More recently, Newcombe (2014) suggested an alternative to the common magnitude account in which development may begin with reliance upon a single system; however, over the course of development, the system diverges into three (or more) separable systems later. Findings of comparable spatial, temporal, and numerical acuity in infancy but not childhood provide support of this notion (see Feigenson 2005; Odic et al. 2013). Further, the substantial evidence of cross-domain transfer in preverbal infants, incapable of verbalizing their strategies on the task, points to the presence of a single magnitude system (Lourenco and Longo 2010). More work is needed to assess the plausibility of a developmental divergence model. Future

work may employ developmental designs to confirm the overlap in space, time, and number in infancy and determine at what point in development these quantities are no longer represented by a common system. Even if a common magnitude system is present in infancy, the implications of such a system are unclear. Are there benefits for representing space, time, and number with a single system? Does using a single system to process quantity free up other cognitive resources for the purposes of other processes? What would provoke divergence across development?

Conclusion

Whether we are choosing the single largest cookie, picking the plate with the most cookies, or estimating how long it takes us to devour the treats; space, time, and number shape our daily life. These quantities adhere to Weber's law and follow similar developmental trajectories, at least in infancy. Further, cross-domain transfer and interference suggest commonalities between magnitude representations. Important differences in these representations do exist, such that unique neural activations are related to specific quantities and emotions impact quantities differentially. In addition, each quantity appears to predict different aspects of formal math. While prominent theories posit that quantities are represented by a common magnitude system (e.g., Walsh 2003), others contend that the evidence supports the existence of separate systems (Agrillo et al. 2013; Odic et al. 2013). Opportunities for research in the realm of space, time, and number are rich as they will continue to inform our understanding of quantity processing, both in the service of understanding the basic processes these quantity representations subserve and in understanding the link to formal mathematical understanding.

Spandrels

Alan H. Krakauer

University of California, Davis, Davis, CA, USA

Synonyms

[Historical contingency](#); [Nonadaptive hypotheses](#)

Definition

In evolutionary biology, an unnecessary adaptive hypothesis for the presence of a trait that is better explained using different levels of analysis.

Introduction

As the field of evolutionary biology and, in particular, behavioral ecology flourished in the 1960s and 1970s, some practitioners became concerned with a perceived over-exuberance in seeking adaptive explanations for every trait and behavior. In “The spandrels of San Marco and the Panglossian paradigm: a critique of the adaptationist programme”, Gould and Lewontin (1979) discussed the limits of natural selection in explaining the function of organismal phenotypes. This influential paper launched a debate about how biologists should ask questions that continues to this day.

In “Spandrels,” Gould and Lewontin proposed that the misuse of and overreliance on adaptive hypotheses for the function of traits stemmed from two related problems. First, they argued against an over-dissection (“atomizing”) of organisms into individual components to be studied in isolation rather than as part of a connected whole. Second they believed that hypotheses based on historical contingencies or developmental constraints were rarely considered as legitimate alternatives to explanations based on naturally selected function. A consequence of these perceived shortcomings was that it became difficult

or impossible to reject a functional (i.e., argument based upon a naturally selected fitness advantage) explanation for the presence of a trait, since when researchers failed to find support for one functional hypothesis, they were tempted to assume the correct functional hypothesis had yet to be tested, rather than considering nonadaptive hypotheses. Gould and Lewontin proposed that integrative studies (which they link to the idea of a bauplan, the organismal blueprint or assemblage of traits that make up a generalized body plan) that emphasize the way traits comprise the design of a whole organism – how it is built over developmental and evolutionary time – are more appropriate for finding and testing these alternatives.

By way of analogy, these authors open “The spandrels of San Marco” with a description of a grand cathedral containing spandrels, architectural elements at the junction of perpendicular arches supporting a dome (Gould 1997). These features are frequently embellished and elaborated, which could lead to functional interpretations for the existence of spandrels that rely on their decorative nature. However, Gould and Lewontin argue that spandrels are best explained as necessary by-products of the structural connection of two arches and can therefore only be fully understood by considering the engineering and construction requirements of the dome as a whole. This has led to the term “spandrel” in evolutionary biology as shorthand for the application of a (potentially incorrect) functional explanation for a trait’s existence that can be (better) explained at another level of analysis.

The publication of “The spandrels of San Marco” prompted a range of responses that included rhetorical critiques, substantive arguments, and even accusations that the “Spandrels” paper was a politically motivated attack on human sociobiology (Borgia 1994; Queller 1995). These replies found “Spandrels” too divisive while minimizing the powerful role of natural selection that most evolutionary biologists accept. While in most cases the rhetorical attacks have subsided, debates about the primacy of functional explanations for adaptations continue. For example,

“adaptationists” (e.g., Reeve and Sherman 1993) tend to place more emphasis on searching for functional advantages conferred by traits while also stressing that functional hypotheses are complementary and not alternatives to hypotheses pitched at mechanistic, developmental, or historical levels of analysis. Importantly, they refute a major premise of “Spandrels” – that behavioral ecologists view all traits as optimally designed. In turn, others (e.g., Autumn et al. 2002) have refined the scientific arguments put forward in “Spandrels” to advocate for an explicitly integrative view of the study of adaptations. As an example, consider the preference of female túngara frogs (*Physalaemus pustulosus*) for males that produce lower-frequency “chuck” calls. Although females benefit from this behavior by obtaining increased fertilization success from mating with larger males with lower-pitched calls, nonadaptive explanations based upon mechanism and phylogenetic history suggest that current functional advantage is unimportant for understanding female preference for lower-pitched calls. Specifically, the female preference for “chucks” and patterns of auditory sensitivity that result in better detection of lower-frequency chucks appears to have evolved prior to the evolution of the “chuck” calls themselves (reviewed in Autumn et al. 2002).

Additional debates focus on the proper form of null models for studies of trait evolution. For example, are there null expectations for the evolution of sexually selected traits and their corresponding preferences that can be seen as nonadaptive (Prum 2010)? Null or neutral models have become central to other biological disciplines such as population genetics and ecology (e.g., Hubbell 2001); in some ways, the “Spandrels” critique can be seen as a precursor to this conceptual development in behavioral ecology.

Conclusion

Although rhetorically unsavory and scientifically unconvincing to many, “The spandrels of San

Marco” served as a warning for behavioral ecologists to ensure their hypotheses are falsifiable, and that nonadaptive hypotheses based on mechanism, developmental constraint, or history should be considered when appropriate functional hypotheses fail to find support. These propositions are not controversial. However, debate continues as to how often we expect existing traits to offer a fitness advantage, and whether demonstrating a fitness advantage is sufficient to suggest that a trait is an adaptation.

Definition

Spanking is a form of corporal punishment. The United Nations Committee on the Rights of the Child defines spanking as a form of punishment that uses physical force with the intent to cause pain or discomfort (2007). Merriam-Webster online dictionary defines *Spank* (n.d.) as a verb as striking someone with an open hand (often on the buttocks; e.g., she would spank him for misbehaving). Spank as a noun is defined as the actual strike on the buttocks itself (e.g., he received a quick spank).

Introduction

Spanking is a form of corporal punishment or physical discipline that is sometimes used by parents, caregivers, and even educators as a tool for addressing inappropriate behavior. It is often used to reduce undesirable behaviors and encourage more appropriate behaviors. It is a form of discipline that has been around for thousands of years and has been used across countries and continents. The effectiveness of spanking is often hotly debated, as is its potential to change from physical discipline to physical abuse. Historically, deference to parental authority contributed to society’s lack of opinion or intervention regarding spanking. However, as children’s rights were recognized and documented, corporal punishment was examined more closely, and the use of spanking

began to be questioned. There are several studies that have examined topics such as the long- and short-term impact of spanking on children, factors that contribute to the use (or not) of spanking as a discipline strategy, and alternative discipline interventions that more effectively address undesirable behaviors. In more recent years, corporal punishment, including spanking, has been considered a public health issue due to the various negative health outcomes that have been associated with it (Gershoff and Grogan-Kaylor 2016). This speaks to the current critical need for parental education about the effects of spanking on children and alternative discipline strategies.

A Historical Perspective

Historically, across civilizations, child protection was not considered a governmental issue but rather was left to individual families. The administration of discipline of children was assumed to be the role and right of the parent. In the United States, animal protection laws preceded and contributed to the development of child protection laws (Lebow and Cherney 2015). In general, societies believed that it was a family's right to determine how to discipline their children, which made individuals hesitant to interfere or intervene. In some countries, this view has largely persisted; however, in other countries, there have been bans on corporal punishment, including spanking.

In 2008, Gershoff compiled a comprehensive document, *Report on Physical Punishment in the United States: What Research Tells Us About Its Effects on Children*, on the status of spanking and its effects on youth. The report provides comprehensive review of the existing literature (at that time) on the effects of physical punishment, including spanking, on children. The document was created to provide information for a variety of individuals who care for, interact with, provide services to, develop services for, or in some way impact children. It was also created for the children themselves. Gershoff's (2008) synthesizing of the literature revealed four distinct conclusions (p. 7):

- There is little research evidence that physical punishment improves children's behavior in the long term.

- There is substantial research evidence that physical punishment makes it more, not less, likely that children will be defiant and aggressive in the future.
- There is clear research evidence that physical punishment puts children at risk for negative outcomes, including increased mental health problems.
- There is consistent evidence that children who are physically punished are at greater risk of serious injury and physical abuse.

As will be illustrated, Gershoff's (2008) findings are still relevant and consistent with findings from research that has since been conducted. It begs the question then, why is spanking still an accepted discipline practice? Do the perceived benefits outweigh the empirically based negative implications of spanking?

Theoretical Framework

There is one theory that has emerged in research to provide understanding about the use of spanking or corporal punishment as a discipline practice, despite overwhelming evidence that suggests it is not an effective tool. The *Theory of Planned Behavior* (TPB) essentially suggests that an individual's intentions and behaviors are a function of three factors: one being personal, one tied to social influence, and the final related to control (Ajzen 2005, p. 117). The personal aspect is one's "*attitude toward the behavior*," be it positive or negative, while the social influence aspect relates to "perception of social pressure to perform or not perform the behavior" (Ajzen 2005, p. 118). So, an individual who was spanked and perceives that they "turned out okay" might view spanking as an acceptable form of discipline. The third element is "*perceived behavioral control*," or the "...sense of self-efficacy or ability to perform the behavior of interest" (Ajzen 2005, p. 118). The individual believes that they are capable of and have opportunities to engage in a behavior. For example, a parent may intend to use spanking as a form of discipline when they view it positively, see it as effective, believe it to be an acceptable practice (e.g., their own experiences, friends who use spanking to discipline), and feel confident they

can use spanking to discipline their child. Generally, when a parent expects positive outcomes from using spanking (e.g., respect from child, improved child behavior), this predicts a more favorable attitude towards spanking and an increased likelihood of using spanking as a form of discipline. Similarly, perceived social support for spanking (e.g., personal experience and outcomes; or local, familial, or cultural norms or acceptance) can also influence the likelihood of using spanking (Taylor et al. 2017).

In a recent study, Flemming and Borrego (2019) surveyed undergraduate students to examine if discipline acceptability could influence the effect of past discipline experiences on future discipline intent; both aggressive and positive discipline practices were evaluated. Acceptability of aggressive discipline practices was indeed found to affect the relationship between discipline experiences and intent. This was also true for positive discipline practices, though a direct effect between positive discipline experiences and intentions suggests that additional factors may also influence the relationship between these two constructs. The findings of this study suggest that TPB is a useful framework for exploring and understanding the use of corporal punishment or spanking, as well as identifying prevention and intervention strategies.

What Is Spanking?

The definition of spanking is inconsistent across entities and researchers, creating challenges in accurately measuring it. Further complicating matters, different terms are sometimes used interchangeably with spanking, such as corporal punishment or smacking. The United Nations (2007) defines corporal punishment as “any punishment in which physical force is used and intended to cause some degree of pain or discomfort” (p. 4). The expanded definition includes the use of an implement (e.g., a whip, stick, belt, or wooden spoon), physical aggression (e.g., pinching, kicking, biting), and other severe and degrading behaviors (e.g., burning, forced ingestion of a substance). Alternatively, some researchers define spanking as non-injurious,

open-handed hitting of the extremities or buttocks with the intention of modifying child behavior (Gershoff and Grogan-Kaylor 2016). These varying definitions complicate discussions about physical punishment. A helpful definition is to consider spanking a form of physical discipline or corporal punishment that uses physical force with the intention of causing a child to experience pain but not injury for the purpose of correcting inappropriate behavior. Spanking is usually differentiated from physical abuse in that physical abuse is use of excessive force that results in injury. However, guidelines for what constitutes *injury* and *excessive force* are often unclear.

Prevalence of Spanking

UNICEF (2014) compiled data on violence against youth, including corporal punishment, from over 190 countries in its publication *Hidden in plain sight: A statistical analysis of violence against children*. The report states that physical discipline from caregivers, including spanking, is experienced by roughly 6 out of 10 children between the ages of 2 and 14 worldwide (p. 97). Spanking was found to be the most common form of physical discipline with about 44% of youth experiencing it. Children ages 5–9 were the most likely to experience violent discipline (which includes violent psychological aggression), though both younger children (ages 2–4) and older children (ages 10–14) were still highly likely to experience some type of physical discipline. It is important to point out that the majority of youth experience both violent discipline and nonviolent discipline (e.g., explaining why behavior is wrong, taking away privileges, redirecting the child).

The International Dating Violence Study gives additional insight into the disciplinary practices of 32 nations. The average amount of adults who recall receiving corporal punishment “a lot” before age 12 was 52.3%. (This data probably does not reflect rates for ages below 5, of which adults have few memories). Taiwan, Tanzania, and South Africa reported rates of corporal punishment over 70%, while New Zealand, Belgium, and the Netherlands were under 20% (Straus et al. 2014).

In the United States, spanking is also a common childhood experience. Corporal punishment in the home is legal, and corporal punishment in the school context is legal in 19 of the 50 states (Global Initiative to end all Corporal Punishment of Children [Global Initiative] 2020b). It is estimated that more than 90% of parents in the United States spank or slap toddlers, with over 30% of these parents reporting the spanking of infants. Spanking continues at a rate of over 50% until age 12 and only drops to 25% by age 16 (Straus et al. 2014). Unfortunately, there is evidence that the majority of substantiated cases of abuse in the United States occur within the context of spanking to correct behavior (Gershoff and Grogan-Kaylor 2016; Straus et al. 2014).

To Spank or Not to Spank: Effects of Spanking

The harmful effects of spanking have been the focus of intense research for several decades. Determining a cause and effect relationship is difficult as experimental designs would often be unethical, and much of the research which examines the effects of spanking is correlational. However, several meta-analyses reviewed many of these studies (e.g., Gershoff and Grogan-Kaylor 2016). There are also longitudinal studies which provide stronger evidence of the relationship between spanking and other externalizing and internalizing behaviors (e.g., Gershoff and Grogan-Kaylor 2016; Mulvaney and Mebert 2007). Overall, the research confirms the association of corporal punishment with increased externalizing and internalizing behaviors. Gershoff and Grogan-Kaylor's (2016) meta-analysis attempted to differentiate between open-handed spanking and more severe forms of physical punishment, and still spanking was associated with more aggression, antisocial behavior, externalizing and internalizing problems, mental health problems, and lower cognitive ability. Additionally, the negative outcomes for corporal punishment are similar in magnitude and direction with physical abuse (Gershoff and Grogan-Kaylor 2016; King et al. 2018).

Externalizing Effects

Corporal punishment, including spanking, is associated with increases in aggression and other externalizing problems such as lying, bullying others, property damage, and cheating (Straus et al. 2014). Immediate compliance and self-control have had a small but positive association with corporal punishment in a few North American studies; however, similar results are also gained through nonviolent disciplinary tactics such as time-outs (Gershoff and Grogan-Kaylor 2016; Straus et al. 2014).

Several longitudinal studies demonstrate increased odds for aggression and antisocial behavior later in childhood, adolescence, and adulthood across North America, Europe, and Asia (Rebellion and Straus 2017; Mulvaney and Mebert 2007). Indeed, these associations remain even after accounting for moderating variables such as race, difficult child temperament, maternal depression, and family income. Research confirms a dose-response relationship. That is, the more frequent the spanking, the higher the odds of externalizing issues (Afifi et al. 2006). In contrast, children who experience no corporal punishment tend to be better behaved, have better relationships with their caregivers, and are less likely to commit crimes or experience addiction (Straus et al. 2014).

Internalizing Effects

According to one US study (Afifi et al. 2012), 2–5% of Axis I disorders (such as major depressive disorder and generalized anxiety disorder) and 4–7% of Axis II disorders (such as borderline or narcissistic personality disorder) can be attributed to the effects of harsh physical punishment (e.g., being pushed, grabbed, shoved, slapped, or hit) even when adjustments are made for family dysfunction and sociodemographic variables such as race and level of education. Similarly, Afifi et al. (2006) found increased odds of experiencing major depression, alcohol abuse, or alcohol dependence. This suggests that corporal punishment practices are potentially inconsistent with the promotion of mental health and well-being. While these findings are from one study, they highlight the importance of considering both the

(potential) short- and long-term impacts of corporal punishment.

Cognitive Effects

Research has found that spanking, and other forms of corporal punishment, increases the odds of lower academic achievement and is associated with failing to keep up with average development of cognitive ability (Straus et al. 2014). It is thought that corporal punishment is a frightening and threatening experience for children that occurs over a long period of time. This stress may disrupt cognitive growth. Furthermore, parents who regularly use spanking as their main form of discipline may be less likely to use cognitive-enhancing verbal explanations when punishing (Straus et al. 2014). Data from the National Longitudinal Study of Youth suggests that young children who do not experience corporal punishment between ages 2–4 increase cognitive ability faster (when assessed 4 years later) than those who have not been spanked (Straus and Paschall 2009). Examining the effects on cognitive ability from a different perspective, Mackenzie et al. (2013) found a negative association between paternal corporal punishment at age 5 and receptive vocabulary in children at age 9. Their longitudinal study also found that spanking at age 1 predicted lower Bayley mental development scores at age 3 (Mackenzie et al. 2013). The research examining the impact of spanking and related corporal punishment indicates that, contrary to popular belief, spanking young children can indeed be harmful to children both in their emotional and cognitive development.

Cultural Considerations on Spanking as a Disciplinary Practice

Cultural factors are important to consider regarding the use of spanking by parents. Many aspects of culture have been researched regarding potential impact on the frequency of use of spanking, as well as on the outcomes of spanking for children. Understanding the relationship between spanking and culture is complex and difficult due to a

multitude of factors, including how researchers define relevant terms such as corporal punishment, spanking, and culture, as well as how confounding variables like socioeconomic status, high-risk populations, education level, and domestic violence may influence research (Gibson and Fagan 2018; Ragavan et al. 2019).

Despite these complicating factors, most literature agrees that spanking is still a frequently used disciplinary technique by parents around the world. Ripoll-Nunez and Rohner (2006) found that 75% of the world's societies use corporal punishment at least occasionally, although the frequency with which spanking is used varies greatly, with only 20% of societies using it often. Research also shows that the negative effects of spanking can be generalized across all countries and societies. In a study of 62 countries, 59 had a negative relationship between the use of spanking and socioemotional development (Pace et al. 2019). Among both high- and low-income countries, spanking is shown to be associated with internalizing and externalizing behavior problems, although the strength of this association appears to be weaker in countries where spanking is more culturally normative (Lansford 2010; Lansford and Dodge 2008; Pace et al. 2019; Wang et al. 2018). This weaker correlation with detrimental outcomes for children may be explained in part by a cultural normativeness perspective, which purports that negative effects may be lesser because a child perceives that spanking is widely accepted in their cultural group. Hence, being spanked may not signify that they are being rejected by their parents or treated in an unduly harsh way (Gershoff and Grogan-Kaylor 2016). Noteworthy, however, is research that also suggests that there is a global association between more frequent use of spanking in a culture and higher levels of societal violence (Lansford 2010; Lansford and Dodge 2008).

Other cultural factors have been shown to predict use of spanking. Household composition is one such factor, where single-parent households are more likely to use corporal punishment than extended-family households (Ripoll-Nunez and Rohner 2006). Immigrant status may also influence likelihood to spank. Ragavan et al. (2019)

report that Latino mothers are less likely to spank if they are first-generation immigrants. This may be because they have had fewer adverse childhood experiences, because they were spanked less themselves (e.g., immigrated from countries where spanking was less normative), or because they have more community- and relationship-level buffers like social support. Religious factors can also influence use of spanking. In the West, conservative Protestantism supports the use of corporal punishment and can even suggest that a parent refraining from the use of spanking may be detrimental to the child (Ripoll-Nunez and Rohner 2006). Furthermore, in Eastern and Western societies alike, the use of corporal punishment is shown to be transmitted across generations. For example, Wang et al. (2018) studied the intergenerational transmission of parenting in Chinese families, where corporal punishment has long been the norm. The intergenerational transmission of parenting is the process (either intentional or unintentional) whereby an earlier generation psychologically influences the parenting attitudes and behaviors of the following generation. This transmission of corporal punishment across generations may be universal in both Western and Eastern societies. People who experienced corporal punishment as children are more likely to approve of the use of spanking as a disciplinary technique and are therefore more likely to employ this technique themselves when faced with their child's misbehavior (Wang et al. 2018).

Within the United States, in particular, culture also plays an important role in understanding the frequency, effects, and prevention of spanking as a disciplinary technique. Much of the research shows that cultural groups tend to influence the frequency with which parents use spanking. In some cultural groups, including the American South, lower SES families, and conservative Christian Evangelical Christianity, spanking is found to be more normative (Lansford and Dodge 2008). Additionally, many studies indicate greater use of corporal punishment in Black families than in White families (Gershoff and Grogan-Kaylor 2016). Data is conflicted regarding the use of spanking in Latino families, with some studies reporting as high as 73% of Latino families using

spanking (e.g., Klevens et al. 2019), and some reporting rates of spanking in Latino families to be less than that of White families (e.g., Ma and Klein 2018). Differences in the use of corporal punishment between racial and ethnic groups have been found to be associated with parental stress, parents' cognitive-emotional processing of children's misbehavior, negative perceptions of the child, beliefs regarding the effectiveness of corporal punishment, the level of importance placed on obedience, and positive attitudes regarding corporal punishment (Klevens et al. 2019). For example, in many Black families, the cultural value of deference to adults is highly esteemed, and therefore, corporal punishment can be considered necessary to correct disrespect. Furthermore, in the United States, a national history of racial discrimination and institutionalized social and economic segregation of Black communities may influence Black parents in low-income neighborhoods to employ parenting techniques such as spanking in order to better prepare their children for the environmental challenges and physical dangers they may face. Other researchers have found that, in Hispanic families, cohesiveness, respect, family harmony, and the mother's role as a caring and nurturing parental figure are highly esteemed values that may contribute to the reported lower rates of spanking in some studies (Ma and Klein 2018).

However, regardless of how culture affects the frequency of spanking among various racial or ethnic groups, most of the literature concludes that the detrimental effects of spanking on children remain consistent (Ma and Klein 2018). Gershoff et al. (2012) studied four racial or ethnic groups in the United States (Hispanic, Asian, White, and Black) and found that, despite differences in the frequency of use of spanking, there were no differences in how spanking predicted an increase in children's behavior problems. Growing research continues to highlight the similarities, not differences, in the association between spanking and adverse child outcomes. This data for cultural groups within the United States appears to contradict cultural normativeness theory, as spanking is associated with the same negative outcomes for all children, regardless of racial or ethnic differences (Gershoff and Grogan-Kaylor 2016).

Alternative Strategies

Regardless of the reason for the use of spanking (e.g., personal history, cultural, contextual), a robust body of research has demonstrated both the ineffectiveness of spanking, as well as the potential harm it can cause. Despite this, parents and even school staff continue to use spanking as a disciplinary practice. This signifies the need for general education and support in identifying positive discipline practices that are effective and support child development. Parents and others who work with children would benefit from education about the potential short- and long-term effects of spanking, as well as alternative nonviolent discipline practices that have demonstrated effectiveness in addressing behavioral issues. Schools that use corporal punishment would also benefit from this information. Finally, families and educators would benefit from preventative strategies that aim to teach desired behaviors and coping skills.

Build Knowledge and Awareness

Research shows that people are more likely to use corporal punishment if they believe that professionals approve of its use (Taylor et al. 2018). Therefore, professionals such as pediatricians, clergy, and mental health clinicians can play a significant role in providing guidance about child discipline practices. These professionals can help to educate parents at office, clinic, or home visits in ways that are culturally sensitive and empirically informed (Gershoff and Grogan-Kaylor 2016). Pediatricians are especially well-poised to provide guidance on child discipline and can give input on the latest research findings regarding the effects of spanking, providing empirically based information rather than personal perspective, on this issue.

These professionals should have the training to provide parents with accurate information regarding the effectiveness, or lack thereof, of spanking, potential outcomes of spanking, typical child development and the impact of spanking, and alternative appropriate disciplinary techniques. Positive alternatives to corporal punishment can include strategies to reinforce (and increase) the

desired behavior, such as clarifying expectations and consequences beforehand and praising for good behavior; and strategies to reduce the undesired behavior such as redirection, removal of dangerous objects, ignoring the behavior, reasoning, taking away privileges, and time-outs to address the undesirable behaviors (Klevens et al. 2019).

Early Education and Intervention

Changing the expected outcome of spanking is also critical to decreasing its use (Taylor and Hamvas 2011). This can be accomplished in a variety of ways. At prenatal and newborn visits, healthcare providers can give information regarding the potential harms of spanking, particularly for 1-year old children (Ragavan et al. 2019). Additionally, providers can create spanking prevention anticipatory guidance interventions which help guide discussions on positive parenting, the harms of spanking, and even in-office training on appropriate discipline choices like time-outs (Ragavan et al. 2019; Sege et al. 2018). Wang et al. (2018) suggests that prevention should also specifically focus on targeting parents who received corporal punishment themselves as children. Exploring and modifying beliefs regarding parental childhood experiences and expected outcomes of spanking may reduce intergenerational transmission of corporal punishment. Teaching parents that corporal punishment is ineffective and possibly harmful for child development, as well as supporting them in the learning and mastery of more appropriate and effective alternative disciplinary methods, could prove to be uniquely effective in reducing the approval of and use of spanking as a parenting technique (Wang et al. 2018). Evidence suggests that these types of parent education interventions are effective in reducing the use of spanking by parents in diverse cultures within the United States, as well as in countries around the world (Gershoff and Grogan-Kaylor 2016).

Gershoff et al. (2017) conducted a review of promising programs and strategies that can be used to change parents' use of physical punishment, such as spanking. One program the authors identified for parents with young children

(suggested ages 1 through 7) is *Play Nicely*. *Play Nicely* is an interactive multimedia program that originally was developed for parents to use in a clinic or primary care setting but now is available online (website: play-nicely.org). The program uses short educational videos (ranging from roughly 5–10 min) that include common parent-child conflict issues and asks users to choose the best solution from a menu of options that includes both physical (e.g., spanking) and nonviolent forms of discipline; feedback is given about the response (e.g., great option, there are better options). In a review of the literature, Gershoff et al. (2017) found that parents who completed the Play Nicely program were less likely to endorse spanking and less likely to have an intention to use spanking in their discipline practices.

Laws and Social Norms

Finally, enacting legal reform and changing social norms can also be effective strategies in the effort to reduce and prevent the use of spanking (Lansford 2010). Perceived social norms are the strongest predictor of having a positive attitude towards spanking (Sege et al. 2018). In order to change social perception of the acceptability of corporal punishment, many countries worldwide are moving to outlaw spanking as a parenting practice. Legal bans on spanking are currently present in 54 countries. Research has shown that bans are correlated with reduction in use by caregivers (Pace et al. 2019). In many cases, the primary purpose of legal banning is not to criminalize parents' behavior but to shift public perception and understanding (Ripoll-Nunez and Rohner 2006). Countries such as Sweden and Finland have accompanied their laws prohibiting spanking with national campaigns to decrease the perceived social acceptability of spanking (Global Initiative 2020a; Ripoll-Nunez and Rohner 2006). However, some argue that given the continued support for spanking in the United States, as well as the fact that the United States is the only country not to ratify the UN Convention on the Rights of the Child, a legal ban on spanking may not be a likely method of reducing the use of corporal punishment within the United States

(Gershoff and Grogan-Kaylor 2016). Mass media campaigns, though, show great promise for shifting public approval of corporal punishment. For example, the Triple P – Positive Parenting Program – is a multitiered intervention which includes a public education campaign (Gershoff and Grogan-Kaylor 2016). Triple P – is used in more than 25 countries and has been shown to be effective across cultures, socioeconomic groups, and household structures.

Conclusion

Spanking is a complex and often controversial issue and is a topic that many people have strong opinions about. In fact, it is a topic that can be polarizing within families and among friends. The controversy surrounding spanking can create challenges in having productive conversations about whether or not spanking as a discipline practice should be supported or condemned. Many individuals might believe that it is a parent's decision and not to be commented upon by outsiders, while others might believe that it should be a community decision. Still others, such as some religious schools, deem it their right, and even responsibility, to use spanking or other forms of corporal punishment as a means of discipline.

The research examining spanking and corporal punishment illustrates the potential for a negative impact with relation to externalizing behaviors, internalizing behaviors (e.g., social and emotional development), and cognitive development and growth. These negative outcomes can occur and persist both in the short-term and over the long-term. It is critical that empirical research related to spanking and corporal punishment is disseminated much more widely so that it is accessible to all individuals. Professionals, such as pediatricians, mental health professionals, or clergy, might not need to tell parents whether or not they should spank their child, but they should at the very least inform parents about the effectiveness (or lack thereof) and the potential outcomes (overwhelmingly negative) of spanking. These professionals then have an opportunity, and one could argue a responsibility, to provide parents

with alternative discipline practices to address the behaviors of concern. Additionally, they should check in with parents about how effective their discipline practices, spanking or otherwise, are at addressing behavioral concerns.

The critical importance of considering the implications and impact of spanking before implementing it as a discipline practice, and even during, cannot be understated. Despite this, spanking is a practice that is often given little thought with regard to the potential negative effects on internalizing behaviors, externalizing behaviors, or cognitive development and growth. It is unclear how parents determine if the practice of spanking is effective, nor if they weigh the value of its effectiveness on a specific behavior or behaviors compared to the negative outcomes that most likely co-occur with any perceived benefits.

The Global Initiative's (2020a) report on corporal punishment indicates that 58 countries have *prohibited* all corporal punishment of children and 30 states (or countries) have *committed* to prohibiting all corporal punishment. Please note that the report refers to countries as states. Examining the percentage of the global child population that is fully protected in law from corporal punishment, 12% of youth are fully protected, 78% are fully protected in some settings outside of the home, and 10% of youth are not protected in any setting. If we believe that children should have rights, particularly the right to protect their body, it is alarming to see the very limited protections that have been enacted to ensure those rights. Contextualizing this information in the context of how we view our children's rights, this data suggests that the overwhelming majority of youth globally are not fully protected from experiencing corporal punishment and therefore have limited say over what happens to their body in relation to discipline, physical discipline in particular.

While spanking is viewed by some as perhaps a less harsh or less harmful form of corporal punishment, a large body of research suggests otherwise. It is important to acknowledge that physical discipline, including spanking, does more than just physical harm. The effects beyond those that are physical may not easily be observed

or understood by parents or caregivers who use physical punishments. This again speaks to the critical need for more education about alternative strategies, dissemination of empirical evidence, and more open conversations about spanking. In addition to a wealth of evidence on the negative effects of spanking, there is much research that supports alternative and nonviolent discipline strategies to address behavioral concerns.

Synonyms

[Cognitive map](#); [Mental map](#); [Spatial navigation](#); [Spatial reasoning](#)

Definition

Spatial mapping is the ability to use a combination of external and internally-generated information (e.g., vision and proprioception) to construct a mental representation of the surrounding environment. It is shared by a wide range of species, from fish to humans, and thought to have ancient evolutionary origins.

Introduction

One of the most crucial cognitive abilities of any navigating individual is to form a *mental map* of its surrounding environment and to figure out how to get from one place to another. Everyday excursions, such as hunting and foraging, can take an individual on a complex path away from home, along which one can easily become disoriented and lost. An external, world-based representation of the environment provides the navigator with the capacity to not only compute one's own location in space but also plan multiple possible routes to one's destination. Such an ability is highly adaptive for the behavioral flexibility it provides,

as goals and paths that are subject to change for a variety of reasons. While it has been argued for many decades that we (and other animals) do indeed possess such *allocentric* representations (Tolman 1948), the precise nature of such spatial computations and their neural underpinnings have only come into light more recently.

Environmental Influences on Spatial Mapping

An important characteristic of our spatial mapping ability is that it relies heavily on calculations of geometric relationships defined by the large-scale structure of the environment (Gallistel 1990). For instance, a disoriented child is able to use distance relationships according to the walls of a room to reliably find her way to a goal location, while being unable to use those same geometric properties when provided by an array of freestanding objects or 2D lines. Objects and surface markings such as colors and texture are used effectively as *beacons*, or direct cues to location, but evidence suggests that relative spatial locations are mapped primarily with respect to extended 3D structures (e.g., boundaries). This pattern emerges early in development and persists until middle childhood, when performance changes with the acquisition of abstract representations of space. It is shared by nonhuman animals, including birds and fish, and proposed to serve as one of the core components of Euclidean geometric concepts in humans (Spelke and Lee 2012).

Why might children have a representation of space that is more attuned to particular properties of the environment over others? There are several possible reasons that could explain the primacy of extended surfaces in spatial encoding. One advantage to representing the 3D structure of the environment is that unlike natural objects and their featural properties (e.g., color, texture, odors), the geometric shape of the terrain is a stable, reliable source of information that does not change significantly throughout the year. Another advantage is that large, extended structures are easier and faster to process globally and does not take up a lot of attentional or perceptual resources.

A third possibility is that because the sensory system is inundated with spatial information, it is much more computationally efficient to organize the input into large-scale 3D layouts and to encode locations with respect to those layouts, rather than to process all of the information (e.g., as in a pixel-by-pixel visual-matching strategy).

Neural Correlates of Spatial Mapping

Spatial mapping abilities would not only have been adaptive to ancestral hominid species but to all animals, long before humans existed. Therefore, to understand the origins of such mechanisms, we must look very far back into our evolutionary history. Most scientists across the field of psychological and brain sciences agree that through a process of natural selection we have been endowed with neural mechanisms that enable us to encode and remember information about spatial location. Nested deep within the medial temporal lobes of the brain, the hippocampus has been identified to be the hub of spatial representation and memory. It is an evolutionarily ancient part of the brain, present across all vertebrates, and it is not coincidentally adjacent to areas such as the amygdala and ventral tegmental pathways which color our memories with emotional valence and reward processes. Although there is some variability in its anatomical characteristics, the functional specialization of the hippocampus for spatial mapping is preserved across species far and wide across the phylogenetic tree. For instance, when the hippocampus is removed or damaged, subjects' ability to compute spatial relationships is severely impaired, while their ability to learn direct cues or to use beacons remains intact (Rodríguez et al. 2002).

In 2014, the Nobel Prize in Physiology and Medicine was awarded to three scientists – John O'Keefe, Edward Moser, and May-Britt Moser – who identified the neural bases of spatial mapping in the rodent hippocampal formation at the single-cell level. O'Keefe's characterization of *place cells* that increase their synaptic activity at specific locations in space (regardless of facing direction of the animal) (O'Keefe and Dostrovsky 1971)

and the Mosers' discovery of *grid cells* that activate in regularly spaced honeycomb-like tiled pattern across the environment (Hafting et al. 2005) provided scientists with a window into the neural processes underlying metric representations of space. Directional and environmental input to place mapping are provided by *head-direction cells* that encode the direction of an animal's heading and *boundary cells* that specifically encode extended 3D structures. These four types of spatial representations are said to provide, at least in part, the basis for a mental mapping, position-tracking system (Barry and Burgess 2014).

The discovery of spatially selective cells in the rat brain is particularly impactful because of its analogy in the human brain and its implications for the way the human mind organizes and processes information. Scientists are currently investigating the extent to which the representations of what is currently known to be spatial cells might serve a more general function, as in encoding other metric quantities such as or even abstract conceptual relations (Macdonald et al. 2011; Constantinescu et al. 2016). With improved methodologies in studying the human brain, it is also possible to investigate whether the mechanisms originally evolved for spatial navigation and memory might subserve higher-level human cognition, such as imagination and abstract thinking (Jacobs and Lee 2016).

Conclusion

The organization of spatial information in the form of a boundary-based mental map is fundamental to a wide variety of distantly related species. Striking behavioral similarities in spatial memory tasks and shared hippocampal neural correlates of those behaviors suggest that spatial mapping has an ancient evolutionary origin. At the same time, however, the vast range of habitats and modalities of perception and locomotion across animals indicate that there must be a divergence of specialized spatial mechanisms in addition to those that are shared and of common descent. Future research must shed light on such differences and the evolution of our own human reasoning about space.

Definition

Within the social structure of bonobos, also called pygmy chimpanzees, the female dominance hierarchy and female-female alliances effectively prevent sexual coercion and dominance of females by males.

Introduction

Sexual coercion is the use or threat of force by males to increase mating opportunities with likely fertile females (Smuts and Smuts 1993). Sexual coercion is a subset of male aggression and is commonly expressed through forced copulation and other violent behaviors. Sexual conflict in the form of sexual coercion may be an inevitable consequence of the divergent evolutionary interests of males and females, where females are more interested in mate quality while males are more interested in mate quantity (Hosken and Stockley 2005).

Evolutionary biologist Robert Trivers' parental investment theory (PIT) offers an explanation for how sexual conflict influences how the sexes evolve and interact. PIT holds that males are

more indiscriminate than females when it comes to selecting sexual partners (Trivers 1974). Particularly in mammals, the reproductive success of females is limited by the time and resources needed to raise offspring so they take greater care in choosing a mate that provides good genes and parental care (Smuts and Smuts 1993). This creates conflict since females are not always receptive to mating. Conflict is mitigated when males court females with “nuptial gifts,” protection, or help in rearing young. However, these offerings are costly. As a lower cost alternative, males may use coercion to overcome female reluctance to mate.

While animals use aggression in nonsexual contexts, aggression and sexual coercion are heavily intertwined in the evolution of sex (Arnqvist and Rowe 2013). Sexually coercive behaviors, which include physical attack, violent restraint, and forced copulation, are surprisingly common and are especially prominent in primates (Parish et al. 2000). Previous studies of baboons and chimpanzees revealed that males behave more aggressively towards fertile females, which shows how this type of behavior is focused on reproductive goals (Baniel et al. 2017). Males attempt to monopolize sexual access to females around ovulation, increasing their chance of reproducing. If these mating behaviors increase reproductive success, then they will be selected for (Smuts and Smuts 1993). Additionally, females ideally seek mates whose genes produce the most reproductively successful male offspring. If sexually coercive and aggressive behaviors yield this, females may be incentivized to allow male aggressors to mate with them, leading to a self-reinforcing sexual selective cycle that is difficult to disrupt.

Special Case of Sexual Coercion in Bonobos

Bonobos have managed to break this cycle indicated by the overall lack of sexual coercion. Male bonobos exhibit limited aggression, which starkly contrasts with the intense aggression reported in male chimpanzees (Smuts and Smuts 1993). Male aggression towards females is rare and is almost

never followed by copulation (Hohmann and Fruth 2003). Because it does not lead to sex or offspring, sexual coercion is not a successful mating strategy for male bonobos. Female targets of male aggression also suffer serious injury after being subject to physical violence (Parish et al. 2000). Thus, female bonobos have developed counter-adaptations to resist sexual coercion, which is highly instructive of the mechanisms that species can employ to manage sexual aggression as a reproductive strategy.

Socio-Spatial Interactions and Social Structure of Bonobos

To understand how and why bonobos are less aggressive than other primates, it is important to examine their socio-spatial interactions. A key aspect of bonobos' social structure is how they form and maintain stable relationships. Less aggression and more matings have been observed when males and females harmoniously engage in close association (Hohmann and Fruth 2003). Since aggression is incompatible with intersexual bonding, males have adapted alternative ways to enhance mating opportunities. Female bonobos benefit from these associations since aggression is prevented while males able to maintain friendly relations with females benefit with improved reproductive success (Wrangham 1993).

These mutually beneficial stable parties may have formed due to bonobos' feeding ecology, which is less competitive than those of other primate species (Hare et al. 2012). Bonobos' habitats exhibit high food density, decreasing the need for competition. Females will routinely feed and travel together, while males are deferent and yield feeding priority to females (Hohmann and Fruth 2003). This may reflect a strategy to increase reproductive success, since females would potentially choose mates based on this deference (White and Wood 2007). This type of deferent behavior is connected to a larger social hierarchy where females consistently dominate males. Within bonobo parties, social relationships are centered around females, which are further structured by a linear, but not unidirectional, despotic rank order (Parish et al. 2000). As a result,

the bonds females share with one another allow them to routinely dominate males beyond just feeding priorities.

Patterns of female coalition formation can be explained by the kin selection theory, where females stay within their natal groups and close kin throughout their lives (Tokuyama and Furuichi 2016). These relationships are critical in shaping social relationships in primates. Female bonobos break from this model by dispersing from their natal groups and forming new coalitions with nonrelatives. These coalitions often do not direct aggression towards other females but males become a target when they exhibit aggressive behavior, especially towards females. This has been observed in both wild and captive bonobo populations, which suggests that female coalitions evolved as a counter-adaptation to cope with intersex competition. Groups of bonobos, which usually include males, headed by females have been seen to charge at both resident and unfamiliar males. Males may risk retaliation from females who are supported by their coalitions and male allies when they attempt to coercively mate.

Role of Nonconceptive Sex and Less Honest Signals About Ovulation

The fact that adult female bonobos that form coalitions outside of their natal groups implies that females replace kinship bonds with social cooperation. Nonconceptive sexual activity is the key to forming new bonds (Hashimoto 1997). Bonobos are the most nonprocreative sexually active nonhuman primate. Male and female bonobos regularly employ genital contact to establish and regulate social relationships. This occurs in most age-sex combinations, even among juveniles. The hypersexuality of bonobos is unique and functions to develop and nurture social relationships, preventing aggression and repairing broken alliances.

In the context of female counter-adaptations to rape, nonprocreative sex can be used for paternity confusion and communication (Wrangham 1993). Paternity confusion refers to interactions where

the female is not fertile but the male acts as if she were. Females benefit from this since they can recruit male aid and prevent potential harm directed towards her offspring while males benefit since there is a slight chance of conception. These sex acts also communicate to third parties the type of bond present between sex partners. For example, female-female sexual activity may communicate that an important alliance has been formed, thereby inhibiting male aggression.

Primate sexual swellings and female receptivity also influence how bonobos navigate mating strategies (Douglas et al. 2016). Sexual swellings typically signal female fertility, which males use to pinpoint ovulation so they can act accordingly to maximize reproductive success. Female bonobos express regular sexual swellings during cycles where ovulation does not occur, making them less reliable indicators of ovulation in comparison to other primates. Due to their variability in swellings, males cannot accurately predict the fertility of potential mates. In species where the timing of ovulation is more predictable, males may mate guard fertile females, a form of indirect sexual coercion, and constrain their ability to mate with others. The variability of female bonobos' swellings may constrain mate-guarding efforts by males and moderate inter-male sexual competition, reducing sexual coercion (Surbeck et al. 2017). This may be akin to concealed ovulation in humans, arguing that these could be adaptations aimed, in part, at the reduction of sex-based aggression.

Self-Domestication Hypothesis

The self-domestication hypothesis offers another explanation for the reduced aggression and lack of sexual coercion observed in bonobos, positing that natural selection against aggression leads to a series of phenotypic changes in some wild animals, similar to the changes experienced by captive animals bred for domestication (Hare et al. 2012). Experiments in domesticated mammals indicate that selection against aggression also brings about a "syndrome" called neotany in which adults retain some aspects of characteristically juvenile

morphology, physiology, and behavior. For example, less aggressive wolves may have gained a selective advantage by being more willing to explore the niche of lives with humans and therefore would have been better able to exploit novel ecological opportunities.

This hypothesis may explain differences observed in wild species with low levels of aggression (Hare et al. 2012). Bonobos, for example, geographically diverged from their chimpanzee-like ancestors approximately 1 million years ago. They had larger niche ranges, more high-quality food available, and lacked competition from other species. The unique social structure and feeding ecology of bonobos may have led to selection against male aggression. Less aggressive males who allied with females and their coalitions were more successful than their aggressive counterparts. Natural selection would have favored males with more juvenilized behavior, characterized by increased adult play and decreased predatory motivation. This is also accompanied by morphological changes such as smaller canine teeth and a juvenilized cranium. Thus, self-domestication may provide insight into the selective forces that allowed female bonobos to establish systematic dominance over males.

Conclusion

The combination of habitat and feeding ecology, female dominance, hypersexuality, and variation in ovulation signals has influenced the psychological evolution of bonobos. These factors have worked in tandem to select against certain behaviors which, in turn, has led to an overall reduction in aggression and sexual coercion amongst bonobos. Evidence for the self-domestication hypothesis grows stronger as more powerful phylogenetic tests are applied to more species that also show reduced aggression and higher social tolerance.

Furthermore, female coalitions have been considered especially paramount for shaping the social lives of bonobos and understanding the scarcity of forced copulation. In humans, males commonly seek to control female sexuality and pursue reproduction through violence. Examining

how female bonobos have developed counter-strategies for sexual coercion shows that above all, strengthening female social alliances and recruiting male allies can decrease vulnerability to male aggression and sexual coercion.

Special Case: Autism

Annemie Ploeger

ASD; Autism spectrum disorder; Autistic disorder

Definition

A neurodevelopmental disorder with two main diagnostic criteria: (a) persistent deficits in social communication and social interaction and (b) restricted, repetitive patterns of behavior, interests, or activities.

Introduction

Autism is a neurodevelopmental disorder with two main diagnostic criteria: (a) persistent deficits in social communication and social interaction and (b) restricted, repetitive patterns of behavior, interests, or activities. Autism has been associated frequently with an impaired Theory of Mind. Theory of Mind is defined as the realization that other people may have different beliefs, knowledge, thoughts, feelings, and emotions from one's own. A seminal article on the association between autism and Theory of Mind was published in 1985

and addressed the question: *Does the autistic child have a Theory of Mind?* (Baron-Cohen et al. 1985). The article revealed that children diagnosed with autism fail to assign beliefs to others and are unable to predict others' behavior, in contrast to nondiagnosed controls and children with Down syndrome. Because the children with autism were not mentally retarded, in contrast to the children with Down syndrome, it was concluded that the impairment in Theory of Mind was independent of the level of intelligence. This suggests that children with autism have a domain-specific impairment in Theory of Mind. This has been called the *mindblindness theory of autism* (Baron-Cohen 1995).

Extreme Male Brain Theory of Autism

Baron-Cohen extended this finding into the *extreme male brain theory of autism* (also called the *empathizing–systemizing theory*, Baron-Cohen 2009). A male brain refers to individuals in whom systemizing is significantly better developed than empathizing. Systemizing is defined as the drive to analyze the working of systems and to derive their underlying rules. Systemizing is closely related to capabilities necessary for engineering. Empathizing refers to the drive to identify another one's emotions and thoughts and to give an appropriate response. Empathizing is closely related to capabilities necessary for nursing and taking care of children and overlaps with Theory of Mind. A female brain refers to individuals in whom empathizing is significantly better developed than systemizing. Consistent with this typology, research revealed that 54% of the male participants were significantly better at systemizing than at empathizing (compared to 17% of the female participants) and that 44% of the females were significantly better at empathizing than at systemizing (compared to 17% of the males) (Goldenfeld et al. 2005). From an evolutionary perspective, Baron-Cohen has argued that good systemizing is associated with using and making tools, and hunting and tracking, and low empathizing with tolerating solitude and aggression, which are considered to be important

characteristics of males in ancient times. Good empathizing is associated with mothering and making friends, which were important skills for females in our evolutionary past.

Baron-Cohen (2009) considers autism as a case of an extreme male brain, i.e., the extreme of a normal male profile. Empirical results revealed that 47% of the people diagnosed with autism showed an extreme difference in scores on systemizing and empathizing tasks, compared to 6% of male controls and 0% of female controls (Goldenfeld et al. 2005). Because of the overlap between empathy and Theory of Mind, these results are consistent with the mindblindness theory of autism. Moreover, the theory has also been supported by neuroscientific studies, showing that activity in brain areas associated with Theory of Mind is reduced in people with autism compared to controls (e.g., Kana et al. 2016).

Alternatives to the Mindblindness Theory of Autism

Despite the empirical evidence, the mindblindness theory of autism has not remained unchallenged. Most notably, some researchers have argued that a deficit in executive functioning, rather than a deficit in Theory of Mind, is the core of autism (for a review, see Russo et al. 2007). Executive functioning is set of cognitive processes – including attention, inhibition, working memory, and cognitive flexibility – whereby behavior is directed and controlled in order to achieve desired behavior. Others have argued for weak central coherence, i.e., reduced global processing and increased local processing, as the core of autism (for a review, see Happé and Booth 2008). In a longitudinal study on children with autism, Pellicano (2010) showed that individual differences in executive functioning and central coherence predicted performance on Theory of Mind tasks 3 years later, independent of early performance on Theory of Mind tasks. Predictions in the opposite direction were nonsignificant. The author concluded that deficits in Theory of Mind are the result of earlier, more domain-general deficits, rather than the cause of autism.

White (2013) proposed an alternative interpretation; she argued that people with autism have difficulties with executive function tasks, because they do not understand the experimenter's implicit expectations for the task. She called this an impairment in Inferring Implicit Information (the *Triple I impairment hypothesis*). People with autism tend to fail on executive function tasks that are open-ended, unguided, and ill-structured, such as card sorting tasks, whereas they perform well on tasks that are explicit, logical, and constrained, such as the classic Stroop task (for references, see White). This hypothesis is consistent with the mindblindness theory of autism. Other authors have argued that, because of the heterogeneity of the symptoms of autism, it is unlikely that this disorder is caused by a single factor. They argue for different, independent factors to explain the different symptoms of autism. This has been called the *fractionation of autism* (Brundson and Happé 2014).

Conclusion

To conclude, there is ample empirical evidence for the hypothesis that autism is associated with deficits in Theory of Mind. However, it remains inconclusive whether Theory of Mind is the core of autism or whether the observed Theory of Mind deficits are the result of other impairments.

Special Friendships Among Baboons

Edward McLester
Liverpool John Moores University, Liverpool,
UK

Synonyms

Pair bonding; Social bonds; Special relationships

Definition

Baboons (*Papio* spp.) form long-term, nonsexual social bonds between unrelated males and asexual females known as “friendships.”

Introduction

Persistent social bonds between group members known as “friendships” have been described in numerous mammals (e.g., capuchin monkeys, *Cebus* spp.; elephants, *Loxodonta africana*; spotted hyenas, *Crocuta crocuta*; dolphins, *Tursiops aduncus*) (reviewed in Seyfarth and Cheney 2012). Typically, these friendships refer to long-term bonds between nonkin that transcend associations formed in sexual contexts (e.g., during mating periods or consortships). Unlike affiliations with other group members, friendships are broadly characterized by high rates of association in close spatial proximity; positive, non-harmful social interactions; and mutual tolerance and physical, emotional, and/or social support (Silk 2002; Palombit 2017).

Long-term social bonds between males and females are not commonly observed in many mammals outside of pair-living or small group-living species. Under these social structures, limited reproductive opportunities and high parental certainty should select for increased investment in mating and parenting efforts by males, resulting in the formation of heterosexual pair bonds. In contrast, primates typically live in large, multi-male, multi-female social groups that provide more mating opportunities and lower rates of paternity certainty. Nonetheless, the formation of heterosexual friendships has been observed in a number of primate species (e.g., chimpanzees, *Pan troglodytes*; Assamese macaques, *Macaca assamensis*; Japanese macaques, *M. fuscata*; rhesus macaques, *M. mulatta*; chacma baboons, *Papio ursinus*; olive baboons, *P. anubis*; yellow baboons, *P. cynocephalus*) (Seyfarth and Cheney 2012). Establishing the adaptive benefits of maintaining such male-female bonds in polygynous and polygynandrous species has become a question of interest in both behavioral ecological and

anthropological theories. Furthermore, given the likely multi-male multi-female social structures exhibited by early hominins, testing hypotheses of how heterosexual friendships have evolved in similar social structures in extant primates can inform on how the strong male-female pair bonding found in modern humans may have first evolved.

Male-Female Friendships in Baboons

Baboons are polygynandrous, mostly female philopatric monkeys that live in multi-male, multi-female groups, and exhibit separate linear dominance hierarchies for each sex. These species provide some of the best-studied examples of friendship in nonhuman primates. The term “friendship” in baboons primarily refers to the social bonds formed between adult males and females that persist beyond the periovulatory period – in contrast to the short-term consortships formed between males and females in estrus. Under the above definition of friendship, positive social interactions between male and female baboon friends include increased rates of mutual grooming, vocalizing, and female tolerance of male alloparenting (Palombit 2017). Friendships are common throughout groups of chacma and olive and yellow baboons in southern and eastern Africa, respectively, although some dynamics vary within groups and between populations (reviewed in Palombit 2017). For example, while it is common for nearly all adult females in a group to have male friends, the opposite is not true – not all males have female friends at any one time. The number of friendships a female engages in can vary both between females and populations – chacma baboon females typically have only one friend, but in olive baboons the number of friendships can extend to three or more simultaneous friendships. In groups where females exhibit multiple concurrent friendships, the number of friendships may also be positively correlated with dominance rank. Similarly, in some yellow and chacma baboon populations, females are more likely to preferentially select male friends with equal or higher dominance

ranks to their own. The instigator of a friendship also varies between populations. In olive baboons, males are the primary maintainers of friendships by initiating grooming bouts and reducing spatial proximity – in contrast to chacma baboons, where females invest a greater effort into maintaining associations (Shur 2008).

Adaptive Benefits of Friendships for Female Baboons

The pervasiveness of heterosexual friendships among multiple baboon species suggests a substantial adaptive significance to the formation of these bonds. For example, infanticide by males is a well-documented reproductive strategy in non-human primates, particularly in immigrating individuals. By killing an unweaned infant, a male can cause the mother to resume cycling sooner, therefore increasing the number of opportunities for fertilization by the infanticidal male. Evidence from two different methodologies support the hypothesis that for female baboons, a key benefit of friendship with a male is protection against infanticide. First, in a study of chacma baboons during which infanticide was a substantial cause of infant mortality (e.g., 38% of infant deaths), playback experiments found that both male and female friends reacted more strongly to the distress vocalizations of friends under attack compared to non-friends (Palombit 1997). Moreover, male friends responded more strongly to the calls of females with infants compared to females following the death of their infant or when recordings included the calls of a potentially infanticidal male. Second, hormonal analyses of chacma baboon stress responses found that while females experienced higher glucocorticoid levels when their group was taken over by an immigrant male, these levels were significantly lower in lactating females with male friends compared to those without (Beehner et al. 2005). Conversely, males with female friends exhibited increased glucocorticoid levels, but males without friends did not. As such, behavioral and physiological responses in both sexes to behavioral cues in friends and the presence of infanticidal males

suggest that female chacma baboons benefit from the active defense of their infants by male friends.

In baboon populations where infanticide by males is less common (e.g., yellow and olive baboons), friendships are expected to protect against nonlethal harassment. A repeat of the playback experiments conducted in chacma baboons found similar results. Despite a substantially lower risk of infanticide, male olive baboons demonstrated similar protective responses toward female friends in distress. In these cases, female baboons appear to benefit from male friends who can defend them from aggression from other group members targeting themselves or their infants (Nguyen et al. 2009; reviewed in Palombit 2017). More specifically, females benefit from greater protection afforded by higher-ranking male friends, because these males can defend against a higher number of lower-ranking males (Shur 2008). This protection should have a direct fitness benefit, as demonstrated by studies that have shown adult females and infants of mothers who are more closely socially integrated to conspecifics of either sex live longer (e.g., Alberts 2019).

Adaptive Benefits of Friendships for Male Baboons

For male baboons, benefits can be grouped under two hypotheses. Under the parental effort hypothesis, males that have sired the infants of female friends should maintain associations in order to protect their offspring and improve infant survivorship. Paternal care by friends is especially prevalent in populations where paternal certainty is higher, because males are more likely to invest in infant protection, even extending to male friends protecting the unborn offspring of pregnant females, which may be susceptible to abortion induced by immigrant males (Baniel et al. 2016; Städele et al. 2019).

Under the mating effort hypothesis, males should benefit from maintaining heterosexual friendships through increased likelihood that a female will select a male friend to sire subsequent offspring. As such, this hypothesis overlaps with

the previous hypothesis of parental effort in that most examples of paternal care likely reflect a form of mating effort if infant care by a male positively influences female mate choice. Nguyen et al. (2009) and Baniel et al. (2016) found no evidence that friendships generate future mating opportunities for males of any relation to infants after their female friends had weaned and resumed cycling. It is possible however that the effect of prior friendships on mating opportunities may vary between males that have sired their friend's offspring and those that have not (Städele et al. 2019) or if increased mating opportunities occur with the same female friend or a different non-friend (Palombit 2017). Moreover, both the aforementioned studies were conducted in yellow and chacma baboons, respectively. In these species, female mate choice may influence male mating success to a lesser extent compared to male dominance rank (e.g., compared to olive baboons). Städele et al. (2019) found a positive relationship between heterosexual sociality and subsequent male mating success in olive baboons, although there was no effect when considering (1) males who had sired the current infant and (2) lactating females (as opposed to cycling females without sexual swellings). In olive baboons, there is therefore likely a complex interaction between the effects of male friendships and rank on female mate choice, although a female's friendships may have a greater influence than male rank compared to other baboon species.

Conclusion

The conspicuousness of male-female friendships in baboons provides an excellent window into the evolutionary significance of sociality among non-kin in nonhuman primates. While several questions have yet to be explored – for example, the effect of friends in deterring predators and for males the possibility that friends facilitate access to grooming networks or infants for use in agonistic interactions – current data already indicate key selective pressures in baboons through which such stable pair bonds may have evolved. In particular, hypotheses of male mating and parental

effort reflect predictions for the origins of pair bonds in early hominins and subsequently modern humans. As such, studies of friendship in baboons, among other nonhuman primates, can provide useful models for inferring ecological and social determinants of human behavior that are not retained in the fossil record.

Specialized Cognitive Skills

[Cognitive specialization](#); [Functional specialization](#)

Definition

“Specialized Cognitive Skills” refer to a set of skills that pertain to specific behaviors and are a product of natural selection and transmission to one’s offspring. These skills are refined over time

to allow for maximum benefit to the individual organism and to facilitate adaptive survival. Some examples of such skills include theory of mind, altruism, sensorimotor skills, and language.

Introduction

The ability to understand someone's intentions, to empathize, or to sympathize is a product of one's environment as well as neurobiological processes responsible for making unique connections in the brain over time. Alternatively, the brain's ability to remember information and make decisions is also a product of one's environment as well as neurobiological processes. Together, these skills represent processes that are interdependent of one another. From an evolutionary perspective, these processes represent both cognitive specialization and functional specialization (Povinelli and Preuss 1995). Cognitive specialization (also referred to as specialized functions) is a result of the brain's ability to be modular, with specific cognitive domains responsible for processing specific types of information (Fodor 1983; Caramazza and Coltheart 2006). Functional specialization refers to the actual neurobiological processes that occur to facilitate cognitive processes (Mahon and Cantlon 2011).

One of the most debated topics regarding specialized cognitive skills is the mapping, or how cognitive processes relate to brain activity (Mahon and Cantlon 2011). To date, two theoretical paradigms attempt to explain this association; however, both are contrasting in nature: the *reverse inference* and *forward inference* approaches (Poldrack 2011; Henson 2006). The reverse inference approach asserts that due to a specific activation in a given brain region, a specific cognitive process emerges (Poldrack 2011). Conversely, the forward inference approach asserts that when a given brain region is activated, a specific cognitive process may occur; however, this same brain region might also recruit an additional cognitive process simultaneously (Henson 2006).

From an evolutionary perspective, cognitive specialization and functional specialization are

both a result of neuroplasticity (i.e., the brain's ability to reorganize and adapt), meaning, they depend on information reorganization, accommodation, and assimilation on a neurobiological level to execute cognitive skills such as theory of mind (ToM), trust, and language and to make use of heuristics in social interactions. Specialized cognitive skills are best understood in the context of social interactions and how they influence an organism's ability to acquire, develop, and evolve these skills in order to ensure survival (Povinelli and Preuss 1995).

Social Cognition and Specialized Cognitive Skills

Adaptive functioning in one's environment is central to the acquisition, development, and evolution of specialized cognitive skills. Such skills are integral when an individual attempts to make sense of their environment, learns, forms judgments, makes decisions, communicates with others, and regulates behaviors. For example, *alexithymia* is a subclinical phenomenon that results in a lack of emotional awareness; specifically, an individual may struggle with identifying feelings within themselves, describing feelings to others, have a restricted imaginative process, and have an external locus of control (Sifneos 1973; Taylor et al. 1999). In context to social cognition, alexithymia is the antithesis of optimal learning, decision-making, communication, and behavior regulation as many who struggle with this condition often experience low levels of happiness and life satisfaction (Timoney and Holder 2013).

The evolution of specialized cognitive skills has been extensively studied using primates, namely, due to their similar cortical cytoarchitecture relative to *Homo sapiens*. For example, the concept of *cooperation* was demonstrated by chimpanzees that reacted to release fellow primates from their enclosure in order to collaborate on a specific task (Gilby et al. 2008.; Melis et al. 2006). The "seeing-knowing" link, aka *theory of mind*, was demonstrated in a group of chimpanzees that observed the gaze of a fellow primate when they were interested in the whereabouts of

another (Premack and Woodruff 1978; Call and Santos 2012; Whiten 2013; Krupenye et al. 2016). These examples refute the notion that only *Homo sapiens* are capable of higher-order perception and decision-making skills in context to a social environment.

Specialized Cognitive Skills and Functional Systems Theory

Functional systems theory (FST) is a theory proposed by Russian biologist and physiologist, Pyotr Anokhin (Anokhin 1974; Red'ko et al. 2004). The theory outlines how various organ systems, including the brain, work in an interrelated fashion and adapt as a result of environmental and neurobiological sensory input and actions (Red'ko et al. 2004). This theory contrasts with the reflexive theory which surmised that behavior was a result of a series of stimulus and responses that followed a linear trajectory (Red'ko et al. 2004). Some examples of FST include swimming, running, swallowing, etc. These examples portray a rather complex orchestration of interrelated anatomical systems cooperating to achieve synchronous activation, and ultimately, leading to a specific behavior or activity (Red'ko et al. 2004).

As humans evolve, so do our behaviors; as such, our behaviors require us to adapt and assimilate new information in order to achieve our goals and execute behaviors. According to FST, there are eight stages for which an organism acquires information and assimilates it to achieve a desired goal or behavior: (1) afferent synthesis, (2) decision-making, (3) generation of the acceptor of the action result, (4) generation of the action program, (5) performance of an action/behavior, (6) attainment of the result, (7) backward afferentation (feedback), and (8) comparison of the result with its model (Red'ko et al. 2004). However, these steps can be broken down into five basic hierarchies: (1) *afferent synthesis* (excitement of the central nervous system), (2) *decision-making*, (3) *action*, (4) *evaluation of results*, and (5) *meeting the needs*. Each of these steps are integral in an organism's ability to

understand language or other forms of communication (e.g., intentions of others), compare the situation and results to goals and previously acquired information, and generate a response such as an emotion or behavior (Red'ko et al. 2004).

Evolutionary Cognitive Neuroscience

To better understand cognitive specialization or skills, one must look at the neural substrates, neurotransmission, and cerebral architecture that are involved in functional specialization. As previously mentioned, functional specialization refers to specific functions of the brain that facilitate cognitive specialization (Povinelli and Preuss 1995; Mahon and Cantlon 2011). When one considers the multitude of cognitive processes involved in a social environment, concepts such as orientation, attention, and social responses come to mind. To underscore these processes, Blumstein et al. (2010) developed a framework of social cognitive neuroscience that explains the interrelationship among brain regions, genes, and brain development as they relate to social perception, attention, decision-making, and social responses.

The framework developed by Blumstein et al. (2010) asserts that social behaviors are mediated by a complex system of neural mechanisms that have evolved over time. The authors iterate that these mechanisms operate on *divergence* (e.g., temporal variations in neuroendocrine mechanisms), *convergence* (e.g., combined functioning of different systems), and *conservation of function* (e.g., use of glucocorticoids to aid in mobilization for fight or flight). The model proposed by Blumstein et al. (2010) was refined by Kosciak and Tranel (2012) with their addition of the *Inferential Brain Hypothesis (IBH)*. This hypothesis asserts that social processes shifted over time resulting in a change from evaluating stimuli based on its intrinsic properties to making inferences of the stimuli based on properties independent of the stimuli (Kosciak and Tranel 2012). The IBH approach helps explain why human brains tend to be much larger than other mammalian brains.

Conclusion

The human brain has evolved to accommodate the ever-expanding amounts of sensory information we come in contact with on a daily basis. The ability for an organism to acquire information, integrate it, and enact a goal-directed behavior is a product of both cognitive and functional specialization. Due to a modular neural system, the human brain is able to process vast amounts of information with specific brain regions dedicated to processing domain-specific stimuli. As a result, the human brain possesses the ability to create higher-ordered meaning from seemingly simplistic information input. Such higher-ordered processes include perspective-taking (aka “theory of mind”), linguistic development, socialization, altruism, and even sensorimotor behaviors. As mankind evolves, so will our brains; some types of sensory input and analysis may become more irrelevant as genetics may alter our neurobiology as a result of habituated responses and natural selection.

Definition

“Specific brain damage” describes the destruction or decay of neurons leading to alterations in cognitive, emotional, and/or behavioral functioning as a result of an acquired or neurodegenerative syndrome. Damage may include focal, local, diffuse, or global neuropsychological impairment involving language, attention and concentration, learning and memory, executive functioning, and visuospatial functioning.

Introduction

The concept of specific brain damage and the resulting neuropsychological alterations associated with it have been documented since the advent of the Edwin Smith Papyrus in ancient Egypt. The Egyptians noted aspects of basic neuroanatomy such as the meninges, cerebrospinal fluid, and the overall cranial structure, as well as notions of abnormal brain functioning such as paralysis due to trauma. From an evolutionary perspective, *Homo sapiens*’ brain has by far the most complex arrangement of cerebral processes than any other mammal. Over time, the hominid brain has evolved to account for the demands in its environment. Different from its predecessor *Homo heidelbergensis* and *Homo neanderthalensis* whose brains measured to be approximately 1100–1200 cm³, *Homo sapiens*’ brain measures at 1400 cm³ to accommodate for

larger brain volume due to the emergence of the neocortex. This brings into question, at what level of the brain (allocortex or neocortex) is most impacted or preserved in the event of damage to the brain? What dysfunction is likely observed when damage occurs at either level?

In the 1800s, brain lesion studies helped elucidate the relative anatomical-physiological relationship of various brain functions as a result of specific damage to a given brain region. Around the same time, the now defunct practice of *phrenology* became prominent due in part to the theories of brain functioning proposed by Franz Joseph Gall. Phrenology sought to account for an individual’s intellectual abilities relative to one’s brain size. Essentially, a person’s intellectual abilities were thought to be proportional to a given brain region which could then be observed based on unique geometric-surface differences of a person’s cranium. Present day approaches in detecting specific brain damage include the use of radiological images such as *computed tomography*, *positron emission tomography*, and *magnetic resonance imaging*, and electrophysiological tools such as *evoked potentials* and *event-related potentials*, as well as neuropsychological assessment.

Brief History of Brain Damage and Neuroimaging

One of the first historical antecedents in delineating brain damage can be traced back to the nineteenth century Italian physiologist, Angelo Mosso who monitored pulsations in the brains of adults by surgically trepanning their skulls. After having his patients engage in mental math calculations, he observed an increase in cerebral pulsations via increased blood flow that led him to conclude blood flows according to function; this technique was named the “human circulation balance” (Mosso 1881). However, this relationship was not formally analyzed and determined until 1890 when Charles Roy and Charles Sherrington expanded upon Mosso’s research (Roy and Sherrington 1890). To understand brain damage, it is better to understand it via the perspective of those who theorized how the brain worked in the

first place. This “what” question eventually propelled the field of neuroradiology by systematically testing hypotheses to determine the “how and why.” The two primary schools of thought were proposed by William James in 1890 (externally driven) and Graham Brown (intrinsically driven) between the years of 1911–1915.

Upon reading Mosso’s work on the human circulation balance, James had postulated that the brain worked as an extravagant “input/output” system driven to meet the demands of one’s environment. In essence, he believed that movement/action was a simple coordination between the sensory demands being imposed on a person whereby a complex system would naturally respond with appropriate action (James 1950 [1890]). Eventually, James’s theory would encourage a neurophysiologist by the name of Charles Sherrington to study the central reflex arc and the corresponding synaptic transmission and integration that drove such reflexes (Sherrington 1907).

In contrast to James’s theory, Graham Brown postulated that organization in the central nervous system was “self-referencing.” He believed that neuronal circuits provided the drive for transmission generation needed to initiate organized movement (Brown 1911, 1914, 1915). This theory led Brown to further assert that movement is intrinsically generated in the absence of sensory input (Brown 1915). In Brown’s pursuit to distinguish functionality, he examined spinal cord reflexology and found that locomotion within the spinal cord operated via autonomous neural networks on one side of the spinal cord that activated muscle movement, while on the other side, it inhibited opposite limbs. He described this process as a “half-paired center” (Brown 1914). Today, we know that he was referencing the various laminae within the spinal cord itself, specifically, the posterior/dorsal column for afferent signal integration and the anterior/ventral column for efferent signal transduction, respectively. Brown’s views of central nervous system organization and research would eventually serve as the basis for much of the modern advances in neuroimaging analysis and detection of neuropathology.

Neuroimaging would finally get its “boost” in 1948 when Seymour Kety and his colleagues at

the University of Pennsylvania measured cerebral blood flow as a result of specific functioning. Kety and his colleagues measured whole-brain activity by using an in-vivo tissue technique on animal subjects called autoradiography, an image on an x-ray film produced by the pattern of decay emissions (e.g., beta particles) from a distribution of a radioactive substance. Kety’s quantitative element would eventually be used in the development of the positron emission tomography scan (Kety and Schmidt 1948).

Up until 1986, it was thought that blood flow was a direct response to the brain’s need for oxygen to metabolize glucose into carbon dioxide and into water for the production of energy. It was thought that functional increases in oxygenated blood changed the ratio of oxy vs. deoxyhemoglobin. It was later discovered by Ray Cooper and his colleagues at the Burden Neurological Institute that patients undergoing evaluation for surgery due to epilepsy showed task-induced focal increases in oxygen availability, an indicator that blood flow increased more than oxygen consumption (Cooper et al. 1975). This discovery would later become the foundation for a contrast agent known as blood oxygen level dependent (BOLD) and eventually used as an adjunct measurement in magnetic resonance imaging.

Methods in the Detection of Specific Brain Damage

While trepanning, phrenology, and brain lesions served as a rudimentary and even barbaric approach to detecting specific brain damage, they laid the groundwork for more modern approaches. Current trends in detecting brain damage include the use of computed tomography, positron emission tomography, magnetic resonance imaging, electrophysiological techniques, and neuropsychological assessment. Each approach adds a unique and highly important element in detecting brain damage on both a structural and functional level. By combining neuroimaging, electrophysiological techniques and neuropsychological assessment, clinicians are better able to determine both structural and functional aspects of an individual’s brain functioning.

Computed Tomography

Before PET and MRI, the X-ray computed tomography (CT) or computerized axial tomography (CAT) was the first modern imaging technique to be used in clinical practice. This technique was first theorized and tested by William Oldendorf in 1958 and created by Godfrey Hounsfield in 1967, and was adapted for hospital use in 1971. It operates by passing a highly focused X-ray beam through an object and recording the object's attenuated response and produces a three-dimensional transaxially tomographic image of that object. Prior to the CT was a more invasive technique called pneumoencephalography, a process that localized mass lesions via removing spinal fluid and replacing it with air to determine the rate of ascension into the ventricles when the patient was in an upright position (Raichle 2000). The patient would be manipulated in space while strapped into a bed or chair so X-ray images could be taken. The CT was the first imaging technique developed; however, it was an anatomical tool that left out the functional characteristics of the brain.

Magnetic Resonance Imaging

The theoretical principles behind magnetic imaging (MRI) were discovered by Raymond Damadian, Felix Bloch, and Edward Purcell in 1946 (Kevles 1997); however, it was not until 1973 when Paul Lauterbur devised a strategy to adapt the applications of nuclear magnetic resonance (NMR) and incorporated it with the capabilities of CT imaging to create what is now known as MRI (Lauterbur 1973). The basis of MRI is complex, but the core principles include measuring the activity and behavior of atoms (protons) in water within a magnetic field. Within a strong magnetic field, protons behave like smaller magnets that align within the magnetic field; when these magnets are disturbed from their equilibrium state by a radio frequency pulse, the X-ray captures these changes over time as these time-dependent changes occur as a function of proton fluctuations within tissue.

Positron Emission Tomography

Seymour Kety implemented a technique using radiographic imaging to determine the attenuation

of emission decay within tissue that would later give rise to the positron emission tomography (PET). In 1951, the idea of measuring the decay of a group of radionuclides and its positron emissions was first suggested by David Kuhl and his colleagues at the University of Pennsylvania. It was theorized that transverse sections of the body could be reconstructed by measuring the attenuation of highly focused X-ray beams projected through the section, then, further localization could be achieved by distributing radionuclides in that section and measure the decay of positron emission which would accurately and quantitatively reconstruct the selected section (Wrenn et al. 1951).

Electrophysiological Techniques

While neuroimaging examines the structural aspects of the brain, electrophysiological techniques examine the relative electrical impulses given off by communicating neurons throughout the brain. The concept of *electrodiagnosis* is concerned with measuring action potentials across the brain; such potentials are a product of intracellular processes involving ion channels that mediate such potentials. Abnormal functioning in these ion channels may lead to irregular or even absent action potentials. Common electrodiagnostic procedures include the electroencephalogram (EEG), evoked potential (EP), and event-related potential (ERP). Invented in 1875 by Richard Caton, the EEG records “surface activity” via specifically placed electrodes that measure relative action potentials in a given brain region. Common reasons for the use of EEG include seizure disorder, sleep disorder, and to determine brain death.

Some adjunctive measures to EEG that examine activity-specific action potentials include EP and ERP. The ERP measures brain waves attributed to a specific cognitive, sensory, or motor event. Measured wavelengths may be singular or multiple, indicating the relative time in signal transduction across the cerebrum. Alternatively, EP measures wavelengths that are attributed to peripheral nerve activity and can be recorded from peripheral nerves, the spinal cord, or the cerebral cortex. Three types of EP include

(1) somatosensory evoked potentials (SSEP), which measure wavelength activity from the upper and lower extremities in peripheral nerves, (2) visual evoked potentials (VEP), which measure cortical wavelength activity attributed to visual input, and (3) brainstem auditory evoked potentials (BAEP), which measure cortical wavelength activity attributed to auditory input.

Neuropsychological Assessment

The advent of clinical neuropsychology and neuropsychological assessment began in the twentieth century with its focus on delineating brain-behavior relationships after the onset of brain damage. The concept of “brain-behavioral relationship” refers to the identification of behavioral, emotional, cognitive, and physical outcomes as a result of damage to part(s) of the brain. The neuropsychological assessment provides a wealth of information to referral sources (e.g., neurologists, neurosurgeons, psychiatrists, lawyers, etc.) where other approaches of detecting brain damage may lack (i.e., neuroimaging and electrophysiological techniques). In context to medicine, the overarching concept behind a neuropsychological assessment is focused on (1) diagnosis, (2) describing the neuropsychological status of an individual, (3) planning appropriate treatments, and (4) tracking efficacy of applied treatment(s). Tests are usually paper and pencil-based; however, there has been an increase in the development of computer/tablet-based measures. Such measures “tap into” various cognitive domains (e.g., attention, language, etc.) that provide the clinician insight into the patients’ relative strengths and weaknesses in a given cognitive domain.

While neuroimaging and electrophysiological techniques can identify temporal and spatial elements of cerebral functioning, they cannot describe exactly “what” is impaired or preserved following an injury to the brain. For example, while Broca’s area is responsible for the motor, or efferent aspects of speech, each person differs ever-so-slightly in where their Broca’s area is located. Thus, not everyone who sustains damage to the left posterior inferior frontal gyrus will necessarily present with a prototypical Broca’s aphasia. This example holds true to other aspects

of the brain that mediate other cognitive functions such as attention, visuospatial functioning, memory, etc. Common approaches in neuropsychological assessment make use of either a (1) “fixed battery” approach or (2) “flexible battery” approach. A “fixed battery” refers to a series of tests that measure various cognitive functions that are uniformly applied to every patient regardless of their presenting problem (e.g., stroke, TBI, etc.). Conversely, a “flexible battery” refers to a series of tests that measure various cognitive functions that are independently selected relative to each patient’s presenting problem. While the “fixed battery approach” tends to be favored among researchers, both approaches in measurement are routinely practiced in clinical settings.

Types of Brain Damage

Specific brain damage can be thought of as being acquired brain injuries, consisting of two types: (1) traumatic brain injuries and (2) nontraumatic brain injuries. Both types of damage are specific in nature, meaning, that they are unique in terms of the pathophysiology that underlie them, and the alterations in neurocognitive functioning specific to the neural damage.

Acquired Brain Injuries

Acquired brain injuries (ABI) can be broken down into two categories: (1) *traumatic brain injuries* and (2) *nontraumatic brain injuries*. Both taxonomies of ABIs may result in little to significant alterations in cognitive, emotional, physical, and behavioral functioning. ABIs may be acute or chronic in nature lasting as little as hours and as long as years. A *traumatic brain injury* (TBI) can be defined as “a disruption in normal brain function caused by external mechanical force” (Gómez-de-Regil et al. 2019). A TBI is often associated with alterations in brain function that could lead to a period of reduced or complete loss of consciousness, post-traumatic amnesia (i.e., a state of disorientation to time, place, and person), and reduced memory abilities for events immediately before the accident (i.e., retrograde amnesia), or events after the accident (i.e., anterograde amnesia)

(Gómez-de-Regil et al. 2019). Etiologies of TBI include falls, motor-vehicle accidents, strikes or blows to the head, assaults, projectiles (e.g., firearms), and “shaken-baby syndrome” in young children. Traumatic brain injuries can be conceptualized as being focal or diffuse. However, most TBIs are heterogenous, often presenting with both focal and diffuse injuries (Greenfield et al. 2008). Associated neurocognitive difficulties include impaired processing speed, executive functioning and personality, visuospatial functioning, language, orientation, and attention.

A *nontraumatic brain injury* (nTBI) is differentiated from a TBI by the fact that the underlying neuropathology is a result of an internal dysfunction rather than an external force being applied to the cranium as in the case of a TBI. The most common forms of nTBI include stroke, infectious disease, seizure, electric shock, tumors, toxic exposure and neurotoxic poisoning, anoxia, metabolic disorders, hydrocephalus, and drug overdose. The effects of an nTBI are similar to a TBI; however, most TBIs tend to affect focal areas while nTBIs tend to affect multiple areas due to the spread of cellular necrosis (Greenwald et al. 2003). Both TBIs and nTBIs range in severity from mild, moderate, and severe as determined by the Glasgow Coma Scale (GCS).

Another important aspect in conceptualizing the pathophysiology of an ABI is whether the injury was primary or secondary, meaning, the insult to the brain was affected directly or indirectly (Graham et al. 2002). Primary injuries result from external mechanical forces that produce deformation of brain tissue and disrupt normal brain function. Common causes of a primary injury are acceleration-deceleration forces, rotational forces, forces generated by blast winds, blunt impact, and penetration of projectile objects. As a result, such an injury can produce damage to neurons, axons, dendrites, glia, and blood vessels. Damage to these aspects of the brain will also result in a cascade of other processes such as focal, multifocal, or diffuse patterns of alterations in cellular, inflammatory, mitochondrial, neurochemical, and metabolic functioning (Graham et al. 2002). Alternatively, a secondary injury occurs as a result of a complication with the

primary injury. Secondary injuries often initiate within hours of the primary injury and include ischemic and hypoxic damage, cerebral edema, increased intracranial pressure, hydrocephalus, and infection, all of which may be reversible (Graham et al. 2002).

Evolution of Pain and Neuroplasticity

Trauma to the central nervous system can evoke pain, an evolutionary function that provides warning to an individual in connection with the accident and onset of disease or trauma. In some instances, individuals possess genetic abnormalities that prohibit them from experiencing pain (i.e., congenital analgesia); as a result, they tend to live shorter lives compared to individuals who possess pain receptors. Darwinian evolution suggests that pain perception has evolved over time in response to *Homo sapiens*’ encounters with their environment. Such encounters would elicit specific nociceptive responses unique to the painful stimulus in question. In other words, this is classified as “good pain” as it either promotes survival or favors the fittest in some manner. Conversely, “bad pain” is not beneficial to *Homo sapiens*’ survival; essentially, pain neither promotes survival nor favors the “fittest.” Some examples of bad pain are chronic neuropathic pain and chronic migraines, conditions that emulate a kind of autoimmune response within the central nervous system. For whatever the reason, evolution has yet to improve the immune system’s response to eliminate such forms of bad pain.

Related to pain is neuroplasticity, a process where the brain is able to adapt and accommodate its structure and function both post-injury and in non-injurious situations. The concept of neuroplasticity thus negates the assumption that the brain is hardwired and functions in a fixed manner. Neuroplasticity occurs both within the brain and spinal cord, mediating both “beneficial” and “harmful” neuroplasticity. Beneficial neuroplasticity mediates neural and spinal mechanisms to adapt to changing demands in the central nervous system. Harmful neuroplasticity can lead to chronic diseases such as central neuropathic pain, tinnitus, spasm, and spasticity, and

is also involved in mediating low back pain, fibromyalgia, and chronic fatigue syndrome.

From an evolutionary perspective, chronic pain conditions are relative to *Homo sapiens*; the structure of our brains have changed compared to the *Homo neanderthalensis*. Specifically, *Homo sapiens* have enlarged primary, secondary, and association visual cortices (V1, V2, V3, V5), as well as greater volume in the temporal and parietal lobes (Pearce et al. 2013). These structures and their related cognitive processes of visuospatial organization, language, and learning and memory are integral in how pain is perceived. Thus, with greater aptitude in these respective cognitive processes, it is understandable that we are more likely to experience chronic pain conditions.

Conclusion

The preceding sections outlined how humanity has identified and tracked specific brain damage over time. This entry has discussed the advent and role of modern techniques in identifying brain damage, specifically the use of various neuroimaging and electrophysiological techniques as well as neuropsychological assessment in providing a holistic perspective in the functional impairments derived from damage to the brain. *Homo sapiens* have undergone cerebral changes as a product of natural selection. It has been well-established that there are some cerebral functions that have been selectively eliminated or bolstered as a result of changes in *Homo sapiens* environment. For example, the orbitofrontal cortex and olfactory bulbs have enlarged compared to our *Homo neanderthalensis* counterpart. Thus, olfaction may have greatly improved as a result of such evolutionary changes. Due to these evolutionary changes, an acquired brain injury affects *Homo sapiens* in a unique manner due to our higher-ordered cognitive processes that grew out of necessity related to environmental demands. Our brains have evolved to experience pain as a result of structural changes involved in the perception of pain. Over time, neuroplasticity has mediated both adaptive and maladaptive alterations in neural functioning that allow us to experience pain, but also to recover from specific brain injuries.

Definition

Friendships among nonkin individuals pose benefits related to survival and reproduction. However, dyadic relationships between any two

individuals are not beneficial because of possibilities to exploit others. Selecting partners who are trustworthy is beneficial compared to forming bonds with exploitative partners. The likelihood that mutually nonexploitative and trustworthy friendships are especially beneficial is supported by the observation that individuals with non-exploitative personality traits tend to form stronger dyadic ties.

Introduction

Universally occurring friendships among nonkin humans are founded on need-based support (Hruschka 2010). Need-based support entails a commitment to support one another in situations that warrant assistance. It can be understood as a risk-pooling alliance to mitigate future uncertainties and predicaments (DeScioli and Kurzban 2009). Because predicaments tend to occur rarely and randomly, and there are few possibilities, if any, to prove *true friendship* by offering support in a time of need (Smith and Ohtsubo, Cross-reference), uncertainty regarding the commitment of the partner also characterizes friendships. In other words, a friend may not be a true friend (one who respects the coalition by helping) but instead a “fair-weather friend” (an exploiter or defector) (Smith and Ohtsubo, Cross-reference). Proposed solutions for this uncertainty include feelings of mutual dyadic irreplaceability that result, for example, from a runaway-like dyadic commitment process (Tooby and Cosmides 1996). Through the results of studies that have considered associations between personality and real-life dyadic relationships, this entry introduces the view that partner selection based on non-exploitative personality traits may be important for explaining the formation of beneficial friendships.

Nonexploitative Personality Traits

Personality traits refer to temporally stable behaviors, feelings, and cognitions through which individuals differ from one another. Traits are moderately heritable as well as moderately

observable by others. Because there are numerous personality traits, they are described by models of personality structure that combine sets of traits under a more parsimonious set of broader traits (factors) based on trait covariation. These broad trait factors are descriptive summaries of various intercorrelated traits, each of which may also have unique etiologies. An important property of personality traits is that they are envisioned as dimensional continuums that range from one pole to another, and these poles are oppositional to each other (e.g., introversion versus extraversion, agreeableness versus disagreeableness).

Current personality models often encompass or especially describe personality traits that span from *dark* to *bright*. These traits are considered highly relevant with regard to interpersonal cooperation and exploitation. Specifically, the dark ends of these personality trait continuums describe interpersonally malevolent, selfish, and exploitive behaviors, whereas the bright ends correspond to cooperative, humble, and non-exploitative tendencies, which are hereafter referred to in general as nonexploitative personality traits. One popular model of personality that encompasses such traits is the honesty-humility, emotionality, extraversion, agreeableness, conscientiousness, and openness to experience (HEXACO) model, which incorporates six broad personality factors. Of these factors, honesty-humility is descriptive of nonexploitation at the high end of the trait and of exploitation at the low end (Ashton and Lee 2007). Another personality trait model, the dark triad, focuses on three types of (non)exploitative personality traits, namely, Narcissism, Machiavellianism, and psychopathy. In this model, high scores indicate exploitation in interpersonal relationships and contexts, while low scores signify nonexploitation. The common variance among these three dark triad traits is also perfectly shared with the honesty-humility element of HEXACO, which suggests their engagement with identical personality phenomena (Hodson et al. 2018). In other words, high scores on honesty-humility and low scores on all dark triad traits are similarly descriptive of an interpersonally nonexploitative personality.

Behaviors in economic games have also illuminated the relevance of these traits for non-exploitation. Honesty-humility predicts active cooperation in dictator and public goods games when it is possible to exploit others (Hilbig et al. 2013). In addition, the trait has been associated with unconditional kindness and trustworthiness in the trust game: independent of how much money a trustor initially gives to a trustee, trustees who were high in honesty-humility returned the highest proportion, and trustees who were low in honesty-humility returned the lowest proportion to trustor (Thielmann and Hilbig 2015). Thus, individuals with a nonexploitative personality also behave accordingly in economical experiments.

Nonexploitative Personality Traits and Friendships

In the case that there are individual differences in personality traits and opportunities to select friends, it is beneficial to choose friends who are nonexploitative. This stands irrespectively of the personality of the actor; trustworthy cooperators are generally preferred. However, unconditional kindness and cooperation might be especially costly (i.e., easy to exploit) if these individuals did not often form friendship coalitions with similar companions who are also nonexploitative. This has also been the general observation in studies of real-life friends; friends tend to be similar in honesty-humility while not systematically similar (or dissimilar) in other broad personality traits (Lee et al. 2009). However, this observation of friendship similarity in honesty-humility is not a sufficient indication that two nonexploitative individuals tend to form friendship relations with each other. Friendship similarity applies to the entire trait continuum on the range from low to high honesty-humility, and it therefore conveys with comparable weight that those who are low in honesty-humility (exploitative personalities) are likely to be friends with each other. However, friendships between individuals with low honesty-humility would be inconsistent with the concept of friendships as beneficial in terms of need-based support, as support following

the occurrence of a predicament is unlikely in relationships of individuals with exploitative personalities.

In addition to examining the similarity of friends in nonexploitative personality trait dimensions, examinations of similarity-based attraction and formation of dyadic relationships have demonstrated that dyadic similarities in two other dark personality traits, namely, manipulateness and egotism, are associated with mutual liking among male military cadets (Ilmarinen et al. 2016). This finding corresponds well to the friendship similarities observed for honesty-humility of HEXACO given that the manipulateness and egotism of the supernumerary personality inventory also occupy the same nonexploitative locations in personality space with honesty-humility (Lee et al. 2005). Further examinations of this association have revealed that the similarity-attraction pattern among military cadets was not present along the entire trait continuum but instead only at the low ends of both manipulateness and egotism (Ilmarinen et al. 2016). Thus, dyadic similarity in personality is only associated with friendships at the nonexploitative ends of these personality trait continuums. This finding highlights that if there are individual differences in nonexploitative personality traits, and if individuals can select partners according to these traits, then similarities in kindness and trustworthiness are likely to influence the formation of dyadic relationships.

However, it remains unknown exactly how nonexploitative personality traits and partner selection can impact the friendship formation process to produce dyadic ties between cooperative individuals. In friendships, feelings of mutual irreplaceability – the end result of a pattern that some have suggested is essential for the evolution of friendships (Tooby and Cosmides 1996) – can result from a runaway-like process or from gradually raising the stakes (risks and benefits) in the dyadic relationship (Smith and Ohtsubo). In view of this, it is possible that partner selection initiates these processes according to individual differences in nonexploitative personality traits. This selection could be enabled, for example, through honest and perceivable signals of trust and caring for others that these individuals project in

interpersonal contexts. The active cooperation and unconditional kindness that are associated with these traits in economic games also support this idea (Hilbig et al. 2013; Thielmann and Hilbig 2015). This partner selection and the benefits of friendships may present additional significance for explaining the evolution of these nonexploitative personality traits. More work is nevertheless needed to understand how this similarity-based friendship formation in nonexploitative personality traits comes to fruition.

Conclusion

The understanding that human friendships are based on the provision of help in times of predicaments suggests that an ability to select nonexploitative partners is beneficial. Real-life friendships confirm this pattern, as individuals who are similar in nonexploitative personalities are likely to have the strongest dyadic relationships. Through trustworthiness and mutual commitment, these connections have the power to become relationships that are characterized by mutual feelings of irreplaceability, i.e., specifically beneficial friendships.

Definition

The psychoacoustic terms “loudness” or “volume” are primarily influenced by the amplitude vibration (or intensity) of a sound wave. Measured in decibels, these terms assess power per unit of area in a vocalization.

Introduction

Human speech is a complex, multidimensional signal used by listeners to make a variety of fitness-relevant decisions. Evolutionary signaling theory predicts that listeners have been selected to attend to those acoustic signals that reveal (on average) honest or accurate information about the signaler (Searcy and Nowicki 2005). Evolutionary psychologists have primarily focused on a single component of speech – fundamental frequency (i.e., the primary determinant

of perceived pitch) – and its information value in intrasexual competitive contexts. For instance, a number of studies have shown that lower fundamental frequency increases perceptions of physical and social dominance (e.g., Hodges-Simeon et al. 2010). Several other components of the voice (including formant frequencies) have been investigated from an evolutionary perspective; however, few studies have examined the information content of *acoustic loudness* in order to elucidate the selection pressures that have acted on this particular aspect of the human voice (cf. Hodges-Simeon et al. 2010).

The psychoacoustic terms “loudness” or “volume” are primarily influenced by the amplitude vibration (or intensity) of a sound wave. Measured in decibels, these terms assess power per unit of area in a vocalization (Baken 1987). Because amplitude is a function of the burst of air that leaves the vocal folds, factors such as lung pressure, lung volume, torso musculature, and vocal fold size contribute to an individual’s vocal loudness (Baken 1987). Therefore, larger and stronger organisms possess the capacity to produce louder sounds, and it is this association that should make loudness a valuable signal in intersexual competition.

Among several nonhuman animals, vocal amplitude is a component of acoustic dominance displays (Soltis et al. 2009). For example, female African elephants produce increased amplitudes along with other vocal cues (e.g., longer duration and steadier fundamental frequencies) when engaging in dominance interactions (Soltis et al. 2009). Conspecifics likely attend to louder vocalizations as a signal of larger body size; however, little research has examined the relationship between loudness and body size or strength. In many territorial primate species, “loud calls” are long-distance vocalizations that serve to protect and increase territory size (and therefore resource and mating access) among males.

Loudness may also play a role in dominance assessments among humans; however, research is somewhat conflicting. Aronvitch (1976) found that both males and females make judgments of others’ dominance based on loudness. Further,

men speak with a louder volume than women (Kimble and Musgrove 1988). Several other studies (Hodges-Simeon et al. 2010; Kimble and Musgrove 1988; Page and Balloun 1978), however, found no association between loudness and judgments of dominance. These inconsistent findings may stem from variable interpretations of the word “dominant” across different studies. Several researchers have suggested that there are two routes to attain status: *physical dominance or dominance*, which is attained using force or the threat of force, and *social dominance or prestige*, which is attained with social acumen, intelligence, and unique skill sets (Henrich and Gil-White 2001).

Research suggests that vocal loudness may be associated with the use or threat of physical force in order to achieve physical dominance. For instance, several studies show that loudness contributes to perceptions of aggressiveness. In one study, researchers manipulated recordings of a female speaker’s vocal intensity, which were rated by male and female college students (Page and Balloun 1978). Results showed that loudness had a significant effect on ratings of aggressiveness, but not on dominance or self-assurance. In another study (Rose and Tryon 1979), actors produced vocalizations at three different intensities (68 dB, 76, and 84 dB). Raters assessed on a scale from 0 to 20 (sub-assertive 0–5, assertive 5–15, and aggressive 15–20). Quieter vocalizations (68 dB) were rated as sub-assertive, whereas those at the 76 dB level were rated as assertive, and loud speakers as aggressive. Results of these studies suggest that listeners may attend to speech loudness in order to assess the speaker’s motivation and intention to engage in conflict. Further, those that are motivated to engage in competition are usually confident in their ability to compete. Kimble and Seidel (1991) asked students to respond to trivia and rate how confident they felt with their answers. Those who felt more confident answered more loudly and with greater speed.

The study of perceived loudness is complicated by an interaction with fundamental frequency, that is, those with lower frequency voices are perceived as louder even when amplitude stays constant

(Baken 1987). Hodges-Simeon et al. (2010) analyzed five vocal parameters of male voices (i.e., mean F_0 , F_0 variation, loudness, utterance duration, and formant dispersion) and then used multivariate methods to assess the independent effects of these different acoustic variables on intra- and intersexual competition (i.e., ratings of attractiveness by females and physical and social dominance by males). Of these parameters, high vocal intensity significantly predicted female ratings of male vocal attractiveness – after controlling for mean F_0 , F_0 variation, duration, and formant dispersion.

Conclusion

Humans – like other animals – use complex acoustic signals when assessing potential mates or rivals, which are then used to make fitness-relevant decisions. Future studies on vocal loudness and dominance should distinguish the different routes to achieve status and use multivariate methods to tease out the independent effects of different vocal parameters on social perceptions.

Sperm Competition

William F. McKibbin

University of Michigan – Flint, Flint, MI, USA

Synonyms

Competitive mating, Sperm allocation

Definition

Competition within a single female between the sperm of multiple males for the fertilization of the ova (Parker 1970).

Introduction

“Winning” sperm competition is largely dependent on a lottery principle. That is, the more sperm a male produces, the more likely it is he will win the competition. Thus, the most fundamental prediction generated from sperm competition theory is that males will produce and ejaculate more sperm as the risk of sperm competition increases (Parker 1982). As the proportion of time a couple spends apart since their last copulation increases, the probability that a man’s partner has been unfaithful, and inseminated by another male, logically increases. Producing more sperm in an ejaculate during copulation following a period of time spent apart from a partner may function to outnumber or outcompete sperm from rival men that may be present in the reproductive tract of the woman. Baker and Bellis (1989, 1993) demonstrated that as men spent more time apart from their partner since their last copulation, the men increased the number of sperm produced in the ejaculate at the couple’s next copulation. Researchers have also identified many possible psychological adaptations to the adaptive problem of sperm competition.

Psychological Adaptations to Sperm Competition

Shackelford and colleagues (2002) were the first to document psychological adaptations that function to decrease the likelihood that a rival man’s sperm will fertilize a partner’s ovum. They found that a man who spends a greater proportion of time apart from his partner since the couple’s last copulation rates his partner as more attractive, reports that other men find his partner more attractive, reports greater interest in copulating with his partner, and reports that his partner is more interested in copulating with him. These effects were independent of relationship satisfaction, total time since last copulation, and total time spent apart. This rules out several alternative explanations for their findings such as “men are simply sexually frustrated.” These perceptual changes may motivate men to copulate as soon as possible with their partner, thus entering their sperm into competition with any sperm from a rival male.

In order to avoid sperm competition or in order to compete more effectively, men may have evolved mate preferences that function to select as short-term sexual partners women who suggest a lower risk of sperm competition currently or in the future. Shackelford and colleagues (2004) found that men’s reported likelihood of pursuing a short-term sexual relationship was lowest when imagining that the potential short-term partner is married, moderate when imagining she is not married but involved in casual sexual relationships, and highest when imagining that she is not married and not involved in any casual sexual relationships. Shackelford and colleagues (2004) interpret these findings to suggest that when selecting short-term sexual partners, men may do so in part to avoid sperm competition.

Sperm Competition and Pornography

Pound (2002) argued that men should find cues of increased sperm competition risk to be sexually arousing because frequent copulation can be an effective method of paternity assurance. Thus,

Pound (2002) hypothesized that men would be particularly aroused by pornography that provides cues of sperm competition. An online survey measuring self-reported preferences as well as an online preference study that unobtrusively examined preferences for particular images also demonstrated results in support of the hypothesis. Pound (2002) argued that the most parsimonious explanation for these findings was that male arousal in response to visual cues of sperm competition risk reflects evolved psychological mechanisms that would motivate adaptive copulatory behaviors in ancestral males exposed to cues of sperm competition risk or female promiscuity. That is, while men may *prefer* cues that indicate no sperm competition risk, they may be especially sexually aroused if they are exposed to said cues. This arousal would facilitate copulating sooner and entering into competition with rival male sperm that may be present.

Subsequent research has also supported Pound's (2002) hypothesis. For example, Kilgallon and Simmons (2005) provided experimental evidence that men who viewed images depicting cues to sperm competition produced more competitive ejaculates than men viewing comparable images in which cues to sperm competition were absent. Recent research by McKibbin et al. (2013) also appears to corroborate Pound's (2002) hypothesis. They demonstrated that men's purchases of pornographic DVDs appear to be influenced by their evolved psychological mechanisms for sperm competition. That is, DVDs depicting cues to sperm competition sold better than those that did not.

Sperm Competition and Female Orgasm

McKibbin et al. (2010) demonstrated an effect of sperm competition on men's interest in partner orgasm. Because orgasm may bias retention of a particular male's sperm (Baker and Bellis 1995), men may benefit by ensuring their partner experiences orgasm with them. McKibbin and colleagues demonstrated that men under greater risk of sperm competition, relative to men under lesser risk of sperm competition, are particularly interested

in ensuring their partner experiences orgasm. In this way, men may be able to ensure their sperm experiences selective uptake, rather than a rival's sperm.

Conclusion

In conclusion, sperm competition theory has provided to researchers a wealth of useful predictions regarding male psychology in particular. Their findings have implications for understanding relationship dynamics, extra-pair copulations, and many other aspects of male psychology.

Sperm Competition Risk and Partner Abuse

Kelly T. Melnyck and Joseph A. Camilleri
Westfield State University,
Westfield, MA, USA

Sperm competition is when spermatozoa from at least two males compete for fertilization, which occurs when a female mates with more than one male in one reproductive cycle. Multiple mating within a reproductive cycle can be costly to females, such as increasing exposure to predators and partner retribution. Recent research suggests there may also be various benefits, including mating with males with better genes, gaining additional resources, confusing paternity to improve offspring safety, enhanced status, diversifying genes, increasing social networks for employment, and replacing a low-quality

mate (reviewed in Mulder and Rauch 2009; Wilson and Daly 1992).

Sperm competition creates a selection pressure that leads to traits that either assist males with successful competition for fertilization or females with choice in paternity. Evidence for such an evolutionary process has been studied in a wide variety of species, including fish (e.g., Stockley et al. 1997), insects (e.g., Parker 1970), birds (Dunn et al. 2001), and mammals (Gomendio and Roldan 1991) by considering how physical, physiological, and behavioral traits could have evolved in response to such competition.

Although early applications of sperm competition to humans have been criticized, there has been increased attention to empirical and theoretical work in this area (Shackelford et al. 2002, 2016; Simmons et al. 2004). One area of human sperm competition that received significant attention is in the context of cuckoldry risk – in species that form pair bonds, this risk occurs when females engage in extra-pair copulation and males unknowingly raise unrelated offspring. Forced in-pair copulation (see ► “Partner Rape” entry) has been hypothesized to function by minimizing the risk of cuckoldry by engaging in sperm competition. Several studies have confirmed an association between female infidelity risk and various forms of male sexual coerciveness towards a partner, including partner rape (Camilleri and Quinsey 2009; Goetz and Shackelford 2009, 2006; Starratt et al. 2008). In particular, the association between infidelity risk and sexual coercion appears to be true only among men, and this association is strongest when there are more recent cues to infidelity (Camilleri and Quinsey 2009).

Other behaviors may have evolved to prevent the need to engage in sperm competition. For example, *herding* (i.e., aggressive separation of women from other men), *sequestration* (i.e., aggressive removal of women from their social group), and *harassment* (i.e., persistent sexual pursuit) may function by minimizing women’s opportunities for extra-pair copulations (see Camilleri and Quinsey 2012). Some evidence supports this notion that female-directed intimate partner violence may be a way to coercively

control a partner's reproductive options. Violent men were more likely to engage in actions that limited the autonomy of their partner (Wilson et al. 1995), sexual jealousy is associated with wife assault recidivism, and infidelity risk is associated with nonsexual intimate partner violence (Hilton et al. 2004).

In summary, some variation in partner-directed abuse may be explained as an evolved response to sperm competition. Though much of the research on sperm competition has focused on nonhuman animals, some scholars are testing its application to human psychology. In particular, abusive actions, such as intimate partner sexual and physical violence, may be an adaptive response to cuckoldry risk by engaging in – or preventing the need for – sperm competition.

Definition

Sperm competition tactics refer to a suite of behaviors designed to reduce the chances of a male being cuckolded.

Introduction

Sperm competition occurs when sperm from two or more males occupy the reproductive tract of the same female simultaneously and therefore compete to fertilize ova (Pham and Shackelford 2015). Across most species, including humans, male reproductive success can be enhanced either through preventing sperm competition or winning sperm competition and achieving paternity. Failure at sperm competition, when it occurs, can result in failure to pass one's genes to the next generation and waste time and resources on biologically unrelated offspring. Therefore, males of many species have evolved tactics to both prevent sperm competition from occurring in the first place and to aid in successful fertilization in the event of sperm competition (Pham and Shackelford 2015).

Precopulatory Tactics

Before the point of copulation with a mate, sperm competition can be prevented or at least reduced. This is mainly achieved through guarding a mate from other males in various ways (Parker 1974). For example, in nonhuman animals with little paternal investment, deer engage in male-male combat with their antlers to ward off any rival males near a female of interest (Kodric-Brown and Brown 1984). Similarly, male elephant seals fight one another to gain access to a harem of females (Haley et al. 1994). Theoretical models have been applied to predict the degree of precopulatory mate guarding males will engage in, with the general finding that as the encounter rate of receptive females increases, the amount of mate guarding decreases. This is due to the possibility of missed mating opportunities. Males can increase reproductive success through

mating with multiple females within one breeding season, if that is possible. If there are limited receptive females, however, male intrasexual competition for the small pool of females will be more intense, and mate guarding is a better strategy to avoid sperm competition (Parker 1974).

Humans form monogamous pair-bonds and demonstrate heavy paternal investment, therefore sperm competition and cuckoldry is more costly to male reproductive success. Psychological tactics have then evolved to avoid sperm competition even before relationship initiation (Pham and Shackelford 2015). When men are selecting a mate, even for the short-term, they exhibit a strong preference for women who display the lowest risk of sperm competition. For example, when measuring arousal between the options of married women, those in casual sexual relationships, and women not engaged in any type of sexual relationship, men consistently show the highest arousal for women who are not currently engaged in a sexually active relationship (Shackelford et al. 2004). Similarly, Mogilski and colleagues (2014) found that men place sexual fidelity in the ideal long-term mate as a higher priority than other desired qualities such as physical attractiveness and emotional investment.

Postcopulatory Tactics

In nonhuman animals, several evolved postcopulatory sperm competition tactics have been observed. Male animals of many species, including insects, primates, and rodents, practice ejaculate adjustment, which refers to adjusting the number of sperm per insemination depending on the current risk of sperm competition. Males often rely on environmental cues to estimate sperm competition risk for this purpose. For instance, if a male notices that many other rival males are near a receptive female, he will inseminate more sperm during copulation with her than if he notices few or no rival males to give himself an advantage in the likely event of sperm competition. Increasing sperm count could outnumber the amount of

sperm from rival males in the female's reproductive tract to facilitate fertilization success (Pham and Shackelford 2015). Another tactic commonly observed in male insects (e.g., dung flies) is to interrupt coitus before the rival has a chance to ejaculate, usually by physically knocking him off of the female and to take that male's place to inseminate the female instead (Parker 1970). Also seen in insects, such as damselflies, is the tactic of semen displacement using specialized appendages (often attached to the penis) to scrape out any rival sperm from a previous copulation before the male ejaculates his own sperm into a female's reproductive tract (Waage 1979). Semen displacement can also be achieved via delayed ejaculation, in which the male copulates longer than normal to displace any previously deposited sperm with his penis before he ejaculates. In many species, prolonged copulation also serves to guard females they have recently copulated with to prevent sperm competition, and in some species, males will physically attach themselves to the female for long periods post-insemination to prevent her from contact with other males (McLain 1989).

In humans, there are similarities in sperm competition tactics used by men. Because sperm competition in humans is most likely to occur via female infidelity, men in long-term relationships attempt to keep a steady supply of sperm in their partner's reproductive tract. To achieve this, men engage in frequent in-pair copulation with their regular partner (Pham and Shackelford 2015). Not only do men try to ensure the presence of their sperm in their partner's reproductive tract at any given time, there is some evidence that men engage in ejaculate adjustment based on objective sperm competition risk. That is, men in long-term relationships inseminate more sperm per copulation with their regular partner as time apart from their partner since the couple's last copulation increases. This increased time away from one's partner objectively signals an increased risk of sperm competition (time for which her whereabouts cannot be accounted; Baker and Bellis 1993). Another tactic reported by both men and their regular female partners during copulation is possible semen displacement through deeper

thrusting when men perceive high risk of sperm competition (Pham and Shackelford 2015).

There is also evidence that men engage in postcopulatory mate guarding, albeit mainly with psychological tactics. Specifically, men in committed, sexually exclusive relationships exhibit jealousy when they suspect their partner has committed infidelity. Male jealousy motivates men to discourage infidelity through performing a range of behaviors including monitoring a mate's whereabouts, forbidding her to spend time with others without him present, and threatening to punish infidelity. In extreme cases, men will physically abuse partners who have been unfaithful or rape an unfaithful partner to quickly introduce his sperm to compete with the rival's. Additionally, male sexual jealousy is the number one cited motive for husbands to murder their wives (Kaighobadi et al. 2009).

Conclusion

Throughout evolutionary history, males of many species have faced the recurring problem of sperm competition. Like ancestral problems in other domains, tactics and strategies have evolved to avoid or reduce the likelihood of sperm competition. These tactics fall in two general categories: precopulatory and postcopulatory. Among non-human animals, mate guarding through physical male-male competition is a common precopulatory tactic to avoid sperm competition while ejaculate adjustment and semen displacement are more commonly used postcopulatory tactics. In humans, precopulatory tactics involve mate preferences designed to avoid high sperm competition risk. Postcopulatory tactics include frequent in-pair copulation, ejaculate adjustment, semen displacement, and behaviors stemming from male sexual jealousy.

Definition

Sperm competition is an intrasexual process in which the sperm from two or more males compete to fertilize a female's ova.

Introduction

Darwin's classic view of sexual selection holds that, controlling for differences in survivorship, variation in the reproductive success of the members of one sex can be attributed to two main processes. First, the members of one sex (usually females) preferentially choose to mate with certain members of the opposite sex (usually males), leading to the evolution of sexual “ornaments,” “seductive” traits, and sexual “advertisements.” Second, members of one sex (usually males) directly compete against each other for access to sexually receptive members of the opposite sex (usually females), leading to the evolution of weaponry. These processes are commonly referred to as female mate choice (or intersexual sexual selection) and male-male competition (intrasexual sexual selection), respectively. Darwin's description of these processes extended no further than the precopulatory stage. In 1970,

however, Geoff Parker (1970) recognized that male-male sexual competition can continue after copulation: if a female mates with more than one male during her receptive period, as is the case in most animal species, then sperm from different males can compete for access to the same set of eggs. And, by analogy with female mate choice, females could also use various mechanisms to bias paternity towards preferred males (so-called cryptic female choice).

Over the last three decades, numerous studies have investigated which male traits are favored by postcopulatory sexual selection (i.e., sperm competition and cryptic female choice). Candidate traits include aspects of the size or shape of genitalia, grasping or clasping structures used during mating, courtship behaviors during and immediately after copulation, mate guarding after mating (to reduce the chances that the female remates), seminal proteins, and other chemicals transferred to females during mating (Leonard and Cordoba-Aguilar 2010; Perry et al. 2013; Peretti and Aisenberg 2015). Here, we focus on the evolution of the sperm component of ejaculates, more specifically the number, type, and quality of the sperm.

Sperm Quantity: The Numbers Game

The single best predictor of male fertilization success under sperm competition is to inseminate more sperm than your rival. Indeed, almost all the current theoretical models developed to study “sperm competition games” (Parker 1998; Parker and Pizzari 2010) explore evolutionary stable strategies for investment into numerical sperm production and maximizing the retention of sperm by females. More importantly, game theory models suggest that increases in sperm size that decrease sperm number will only be favored under restrictive conditions (Snook 2005). Below we describe game theory models that predict ejaculate size and then, where applicable, review the evidence from: cross species comparisons (phylogenetic comparative analyses); creating a scenario in the laboratory, such as variation in the level of multiple mating by females

that should affect the strength of sexual selection, and then watching evolution unfold (experimental evolution); studies of changes in ejaculate size under different conditions, such as mating with a virgin or nonvirgin female (phenotypic plasticity studies); and studies of differences in sperm production and ejaculation strategies between different male mating types, such as large, socially dominant males and smaller, “sneaky” males.

Game Theory Models of Ejaculate Size and Expenditure

Mathematical models – predominantly gametheory models – have provided a solid base from which to predict the evolutionary stable strategy (ESS) (i.e., the most profitable outcome given the decisions taken by other males in the population) for ejaculate expenditure (E) or ejaculate size (s). These models cover a wide range of biological scenarios, and, for example, vary in whether fertilization is external or internal; whether male-female interactions affect sperm survival; whether or not competing males are related; the extent to which sperm properties (e.g., size, survival, swimming speed) or other ejaculate chemicals affect fertilization success; whether there is an effect of females being virgins or having already mated; whether females vary in quality; whether males vary in the individual costs associated with mating and/or in the resources they have available to invest in reproduction; whether males switch between different mating roles or have a fixed mating role for life (i.e., social mates vs. unpaired males), when roles differ in how initial ejaculate size translates into relative fertilization success (i.e., favored and disfavored mating role with respect to the likelihood that a given sperm will end up fertilizing an egg); whether males have perfect or imperfect information about the risk of sperm competition; how males respond when the risk of sperm competition or the intensity of sperm competition is above or below the population average; and, finally, whether the model allows feedback so that ejaculate size affects the mean level of sperm competition (Parker 1998; Simmons 2001; Parker and Pizzari 2010).

Most mathematical models assume that a male has a fixed amount of resources R that are allocated to reproduction. These resources can be divided between investment into obtaining mates (where C is the cost of mating) and investment into larger ejaculates (where D is the cost per unit of ejaculate). A male's lifetime fitness is the product of the number of times he mates and his average fertilization success per mating. The ESS is the ejaculate size (s^*) that maximizes lifetime fitness when all males pursue the same investment strategy in the equivalent mating context (i.e., the strategy can include tailoring the ejaculate size to the specific mating context, such as a virgin vs. nonvirgin female). Clearly, mating success will increase under precopulatory sexual selection as more resources are devoted to traits that increase access to mates (e.g., weapons or ornaments) (Parker et al. 2013); while a larger-sized ejaculate will increase a male's average fertilization success under sperm competition.

The models vary in how ejaculate size predicts relative fertilization success. The simplest models assume a raffle-like process, whereby a male's relative numeric share of the competing sperm determines his success: the more sperm per ejaculate, the higher a male's fertilization success ("fair raffle"). Modifications to this assumption are then made to account for cases where the raffle is "loaded" so that certain mating roles have a higher likelihood of fertilizing eggs. That is, some male's sperm are more likely to enter the "fertilization set" of sperm that can then compete for eggs in a raffle-like manner. This differential likelihood of fertilization could arise due to: mating order effects (e.g., first or last-male sperm precedence), temporal effects (e.g., if sperm are steadily lost from the female's reproductive tract after ejaculation, then mating shortly before eggs are fertilized is advantageous), or positional effects (e.g., guarders release sperm closer to the eggs and/or moment of egg release than do sneakers). With a few exceptions, the models do not assume that females favor fertilization by specific males (i.e., there is no cryptic female choice).

If there were no constraints, males would produce an infinitely large ejaculate to numerically swamp their rivals. But because sperm production

incurs nontrivial costs males should facultatively adjust their investment in ejaculates depending on the likely benefits (Wedell et al. 2002). This facultative adjustment in sperm production (or generation of specific sperm traits) is known as "strategic ejaculation." Given finite resources, males should also experience an energetic trade-off between ejaculate expenditure and investing in morphological and behavioral traits that increase mate acquisition (Parker et al. 2013). Indeed, males are known to become sperm depleted, so there is a demonstrable direct trade-off between the number of matings per unit time and fertilization success per mating under sperm competition. For simplicity, most models assume that all males have the same resources R available to invest into reproduction and pay the same costs for ejaculate production or to obtain a mating. The main exception is in models where males are divided into two discrete classes that vary in the average level of sperm competition they experience so that the ESS for each class is predicted. Recently, however, models have been developed that allow for continuous variation among males in available resources and/or variation in the costs paid to elevate mating rate/ejaculate size (Parker and Pizzari 2010). Lower costs of mating lead to a reduced investment in ejaculates because the comparative rate of return from increasing the mating rate more than compensates for a lower fertilization rate per mating.

Broadly speaking, sperm competition game models are divided into those that consider sperm competition risk (whether or not it occurs) or intensity (the number of ejaculates competing for a set of eggs). The "risk" models investigate the effect of variation in q (the probability that two ejaculates compete). Note that early models use an alternate formulation with p , which is the probability that an ejaculating male will face sperm competition from another male [$p = 2q/(1-q)$] (Parker 1998). Risk models are usually envisaged in terms of internal fertilizers and the likelihood that a female will mate twice, while "intensity" models are framed in terms of external fertilization and variation in the number of males (N) ejaculating when a female spawns. They can, however, be applied to both fertilization

modes. Treating risk and intensity separately is a mathematical convenience as the two actually “overlap” (e.g., they should produce the same predictions when $q = 1$ and $N = 2$). Williams et al. (2005) argue that the distinction between the intensity and risk of sperm competition is untenable because the two factors depend on the mean and variance in female mating rate. Risk and intensity are not independent variables if they covary, as is the case, for example, when the number of matings per female approximates a Poisson distribution (see also Fromhage et al. 2008). Engqvist and Reinhold (2005) provided a concise, cautionary account of why treating risk and intensity as independent is problematic when empirically testing models. Their main point is that assumptions have to be made about whether an experiment alters the perceived risk *or* intensity of immediate sperm competition *and/or* the future expectation of the mean level of sperm competition. That is, an experimental treatment with more males per female increases the immediate intensity of sperm competition and the likelihood that a female will mate with at least two males (i.e., risk).

The main prediction of both risk and intensity models is that as the mean risk or mean intensity of sperm competition increases the proportion of the total reproductive effort per mating devoted to ejaculate expenditure ($E = Ds/(Ds + C)$) increases. The rate of increase in E is, however, linear as risk increases but asymptotic as intensity increases (Parker and Ball 2005). E is an index of sperm demand and often estimated empirically by calculating relative testis size (Parker 2016) (i.e., assuming that testis size is a measure of sperm production capacity). The optimal value of E with a fair raffle is $E^* = q/2$ or $(N-1)/N$ (Parker 1998; Parker 2016). This predicts that the mean value of E will be greater in species with a higher mean level of sperm competition. However, if there is a loaded raffle, the payoff to investing in a given mating decreases so that E^* (total reproductive effort) should decline (Parker and Pizzari 2010). Consequently, in taxa where there is strong first or last male fertilization advantage, variation in the risk of sperm competition among species should have little effect on E^* . If a male is in the favored

position, he already has high fertilization success so there is little to be gained by investing more into the ejaculate, and if he is in the unfavorable position, the large amount of additional sperm he would have to produce to substantially increase his fertilization success becomes prohibitively expensive. Relative ejaculate allocation should therefore be lower under the loaded raffle versus a fair raffle.

The magnitude of E^* depends on whether males occupy roles randomly or consistently (although this is obviously an analysis of the extremes of a continuum). If roles are random, males produce the same-sized ejaculate even when they are in the disfavored role (e.g., mating second when there is sperm precedence) ($E^*_{\text{favored}} = E^*_{\text{disfavored}}$). This occurs because the benefits of increasing ejaculate size when a male is in the disfavored role (to counter the lower share of paternity) exactly balance the costs of so doing (fewer resources to invest in future matings where there is an equal chance of being in the favored role). In contrast, when roles are nonrandom, as in the case of alternative mating morphs, there is selection for males in the disfavored role to produce larger ejaculates (Parker 1998; Parker and Pizzari 2010) ($E^*_{\text{favored}} < E^*_{\text{disfavored}}$), assuming that the costs of sperm production do not differ between roles.

An asymmetry among males in the information that they have about q should affect E^* . Parker (1998) and Parker and Pizzari (2010) envisaged two scenarios: each male mates with his social mate and engages in an extrapair copulation (EPC) with some fixed probability or males either play the role of guarder or sneaker. In both cases, certain males (sneakers or those performing an EPC) “know” that there will be sperm competition once they ejaculate ($q = 1$), while other males only know the average risk of sperm competition (mean q). The predicted E^* is greater for males that know there will be sperm competition (e.g., sneakers), although the difference in E^* will be vanishingly small when the probability that mating involves a sneak is very high (i.e., as mean q approaches 1). Finally, males might have information about whether q is above or below average for a specific mating event (i.e., an opportunity for

strategic ejaculation). This has been modeled in the context of a female's mating status or propensity to remate, but it is also relevant when males can use social cues (e.g., the presence of rivals) to estimate the likelihood of sperm competition. If the likelihood that a female mates twice is q then when a male has perfect information about a female, E^* varies between the minimum required to fertilize her eggs if she will mate once and $(1 + q)/4$ when she will definitely mate twice. More realistically, if males can distinguish between virgins (some of whom will not remate) and mated females then for all mean values of q (except 0 and 1 where the likelihood of remating is known) E^* is greater when mating to a mated female ($q/[1 + q]$) than a virgin female ($q/2/[1 + q]$) because the expected level of sperm competition is higher (Parker and Pizzari 2010; but see Kelly and Jennions 2011).

In species where most breeding events involve sperm competition (i.e., most females mate multiply or group spawn so that $q \approx 1$) within-species "intensity" models predict how ejaculate size changes with the number of males (N) per spawning event. Unlike the case for an increase in sperm competition risk within a species, or of mean risk/intensity across species, the prediction is that E^*_i decreases as the number of males competing in a given reproductive event increases beyond two. For example, if males have perfect information about the number of rivals, N_i , and the distribution of males per reproductive event follows a Poisson distribution with mean N_m then $E^*_i = N_m(N_i - 1)/N_i^2$. There is an increase in E^*_i as N_i goes from a solitary male without sperm competition so that s^* is the minimum required to fertilize eggs to a maximum when there are two males (i.e., the risk of sperm competition q goes from 0 to 1), but thereafter as N_i increases, E^*_i declines. This occurs because the value of each sperm released is diminished: the number of eggs available remains constant while the total number of sperm (due to the participation of more competitors) increases. Consequently, the marginal returns from the release of additional sperm are reduced, so the optimal ejaculate size is smaller (Parker 1998). In short, males are better off "saving" sperm for a future breeding event with fewer

competitors. Despite this decline in ejaculate size, however, after taking into account the greater number of matings that males must be engaging in when the intensity of sperm competition is higher, the mean investment in sperm expenditure E^* still increases with the average intensity of sperm competition (i.e., N_m) (Parker 2016).

At the within-species level, several models have investigated how mating roles and/or other predictable deviations of q or N from the species/population mean affect the optimal ejaculate size (s^*) for a given mating event. For simplicity, "risk" models consider cases where there are only two mating roles (favored and disfavored), males "know" their mating role and females mate at most twice. The focus is therefore on s^* when the probability that sperm competition is present or absent changes. Results are, however, usually presented in terms of E^* because it is a unitless parameter useful for comparison across species or morphs. In addition, relative testes size is a measurable trait that is assumed to be positively correlated with E^* if there is selection for larger testes size when the product of the "sperm demand" per mating and the mating rate is higher. Relative testes size can, therefore, be used to test predictions about E^* only in cases where E^* represents the mean sperm allocation for a species or population (Parker and Pizzari 2010).

Parker and colleagues' early models did not consider how, given limited resources and a cost to mating, increasing s^* will decrease the maximum number of matings in which a male can participate ($R = N_m(s + C)$, where N_m = number of matings) which lowers the mean intensity (i.e., N_m). Crucially, this also changes the variance in the number of mates per female, hence the likelihood of sperm competition (i.e., q) thereby creating a feedback loop that affects s^* (Williams et al. 2005). Given the feedback affects both N and q , sperm competition risk and intensity cannot be separated. Williams et al. (2005) allowed the sperm allocation strategy to evolve by varying the resources available for reproduction. They then explored the consequences for mean s^* under various scenarios (E^* was not presented). For simplicity, they did not model strategic ejaculation and only explored cases where ejaculate

size per mating was constant across a male's lifespan (i.e., evolution in response to mean sperm competition level). Their model produced two novel predictions that differed from those of earlier models. First, in populations/species where the total resources that males can allocate to reproduction R increase, s^* increases. Greater R increases the maximum number of matings per male, which increases the number of multiply mated females (and hence sperm competition), which elevates s^* . Second, in agreement with Parker (1998; Parker and Pizzari 2010) the model predicted that s^* increases as the cost of mating increases when there is a fair raffle, however, with a strong mating order effect s^* actually decreases. This occurs because a higher mating cost initially selects for a larger ejaculate, but this decreases the number of matings per male, which lowers sperm competition levels and favors a smaller ejaculate. The relative strength of the two opposing forces of selection on s^* depends on the fairness of the raffle. When the raffle is loaded, the gains from a higher mating rate can outweigh those from greater fertilization success per mating. The wider implication of these results is that variation in mating costs among populations/species could, somewhat counter-intuitively, lead to greater sperm competition risk/intensity being associated with lower s^* .

More recently, Fromhage et al. (2008) pointed out that an implicit assumption in Williams et al.'s model is that males determine the female mating rate which generates the feedback between the level of sperm competition and s^* . Fromhage et al. (2008) therefore modeled the effects of variation in female resistance to unwanted mating attempts. Encouragingly, their model captures the essence of the models of Williams et al. and Parker and colleagues. They show that these earlier models produce results that lie at the ends of a continuum. When female resistance is absent, they obtain comparable results to Williams et al. (2005), and when resistance is strong they produce results comparable to those of Parker's classic models. For example, when female resistance to excessive mating is strong, s^* tends to increase with greater mating costs. The model also shows that as the mean risk of sperm competition

(q) increases s^* can increase, decrease, or remain unchanged depending on the level of female resistance. As the mean intensity of sperm competition (N) increases s^* can decrease or reach a maximum at an intermediate level of N that depends on the level of female resistance. Even so, the classic predictions that E^* decreases with greater mating costs and increases with a greater risk or intensity of sperm competition holds regardless of the level of female resistance. Finally, Engqvist and Reinhold (2007) produced a model predicting that variation among males in their sperm reserves creates a difference in the direction of the relationship between ejaculate size and sperm competition intensity: the relationship is negative for males with small reserves and positive for those with large reserves.

Resolving Areas of Confusion

The development of numerous sperm competition game models has generated confusion about what predictions should be made when conducting empirical studies of strategic ejaculation (Engqvist and Reinhold 2005; Parker and Pizzari 2010). The most obvious concern is to make sure that the predictions being tested are not derived from a model referring to the mean level of sperm competition (i.e., a species-level model). More specifically, there is sometimes a failure to answer two key questions to ensure that the correct prediction is tested: (i) What is the measure of ejaculate expenditure (i.e., s or E)? and (ii) Does the scenario or experiment involve a change in the risk *or* the intensity of sperm competition?

- (i) A distinction must be drawn between ejaculate size s and relative expenditure on ejaculates per mating E . Species-level risk and intensity models make different predictions about how ejaculate size changes with sperm competition: E (and relative testis size) increases as the mean levels of sperm competition risk and intensity increase (Parker and Ball 2005); however, ejaculate size (s) increases with the mean risk of sperm competition ($s^* \propto q/(1+q)$) but declines with intensity when the mean number of competitors (N) increases beyond two males

($s^* \propto (N-1)/N^2$) (Parker and Ball 2005). Fromhage et al. (2008) extended these models by varying the cost of mating and by including female resistance to excessive matings, which influences risk levels by modifying the variance in female mate number. They predict that s^* can increase, decrease, or remain unchanged depending on the level of female mating resistance (Fig. 2a in Fromhage et al. 2008). Similarly, when the cost of mating varies, s^* either decreases or reaches an intermediate peak then decreases as N increases. Predictions about ejaculate size changes are therefore less straightforward than they once appeared. Even so, Fromhage et al. (2008) support the standard prediction that E increases as sperm competition risk or intensity increases.

- (ii) The conceptual distinction between the “risk” and “intensity” of sperm competition is theoretically worrisome and might be empirically intractable. For example, intensity models show that ejaculate size increases when there is a shift from no rival to one rival male and then declines as additional competitors participate. However, the very possibility of there being no rival means that there is a probability that can be attached to whether or not sperm competition occurs (i.e., the risk is less than 100%). Parker (1998) has noted that risk and intensity models represent two extremes and that one would ideally use a probability distribution of the number of competing ejaculates per breeding event. Unfortunately, this has to be calculated empirically or based on assumptions about how males and females interact (e.g., the use of Poisson distributions by Williams et al. (2005) who assume that males control whether mating occurs).

Engqvist and Reinhold (2005) highlighted that there is currently a theoretical grey area where the risk and intensity models meet. We know ejaculate size will increase with a greater risk of sperm competition, but once sperm competition is certain it will decline as the intensity increases. The question is therefore one of determining the

position of the “peak” ejaculate size. This is an important question because it can be almost impossible in experiments to know whether a manipulation (e.g., the presence/removal of a rival male) has altered the focal male’s perception of the risk and/or the likely intensity of sperm competition. First, varying the number of potential competitors could alter both factors if the likelihood that a given male competes is less than one (Pitfall2 in Engqvist and Reinhold 2005). Second, a manipulation might affect the focal male’s perception not only of the immediate risk/intensity of sperm competition but also of the future mean risk/intensity (Pitfall1 in Engqvist and Reinhold 2005). This is problematic because changes in the immediate and the future intensity of sperm competition create opposing selection on ejaculate size. An increased future (hence mean) value generally selects for larger ejaculates (Fromhage et al. 2008; Parker and Pizzari 2010), while an increased immediate value selects for a smaller ejaculate (Parker 1998). The combination of uncertain theoretical predictions at the risk/intensity interface and practical problems in designed experiments makes it difficult to design experiments to test specific models of strategic ejaculation. In practice, using meta-analyses to summarize the empirical results obtained for specific experimental designs might provide insights into how different set-ups affect male’s perception of sperm competition levels.

Evidence that Sperm Competition Favors Greater Sperm Production

The most widely invoked evidence that sexual selection favors greater sperm numbers comes from comparative studies. Sperm production is usually defined as the proportion of reproductive resources invested into ejaculates (E) and is often empirically measured as relative testes size (i.e., corrected for body size) (Parker 2016). Ejaculate size (s) and relative testes size need not evolve in the same direction across species, although earlier game theory models did not make this clear (Parker 2016). The ESS for ejaculate size depends on the level of sperm competition, which depends

on how often females mate. The ESS for sperm production, hence E , depends on ejaculate size and the male mating rate. But, given that every mating involves a male and female, if males mate more often, so do females. This means that the male mating rate and ejaculate size are linked because the higher the male mating rate the greater the level of sperm competition.

The crucial factor in determining whether there is a positive correlation in changes in relative testes size and ejaculate size across species is whether variation in sperm competition is mainly associated with the risk of its occurrence or the intensity of competition. As described earlier, the marginal returns (i.e., change in fertilization success) with each additional sperm diminish as the number of rival sperm (i.e., number of rivals) increases – so the ESS ejaculate size actually decreases as the intensity of sperm competition increases. In contrast, the returns on each additional sperm continue to increase monotonically as the risk of rival sperm being presented increases – so the ESS ejaculate size increases with the risk of sperm competition. The net result is the prediction that ejaculate size will increase with greater *risk* but decline when the *intensity* of sperm competition increases (a prediction that is often assumed only to apply within-species) (Parker 1998; Parker and Pizzari 2010). Predictions about the species level relationship between ejaculate size and sperm competition, therefore, depends on whether the general level of sperm competition is low or high. Many researchers are seemingly unaware of this prediction, perhaps because it was not clearly stated in Parker's early papers. In contrast, the ESS for sperm production, hence E , increases with the level of sperm competition regardless of whether there is a change in the risk or intensity of sperm competition. Even though it depends on both ejaculate size and the male mating rate the effect of the later is more important.

The distinction between relative expenditure and ejaculate size should be borne in mind when interpreting studies of relative testes size. Relative testes size is a common index of ejaculate expenditure, and there is good evidence that larger testes, with a presumably greater mass of sperm

producing tissue, increase sperm production (sperm per unit time) (Parker 2016). This relationship is reassuring given that simple measures of testes mass do not take into account the potential for mass independent variation in sperm production (i.e., production rate per unit volume), changes in the ratio of sperm-producing tissue to other tissue types, and any effects of sperm size on testes size (Parker 2016). In contrast, the relationship between relative testes size and individual ejaculate size (corrected for body size) is less certain. For example, sperm number per ejaculate can be increased via changes in the social environment without a change in testes size in mice (Ramm and Stockley 2009) and, more generally, this is always the case whenever there is strategic ejaculation and ejaculate size changes in response to the local mating context. Ideally, studies investigating selection on ejaculate size need to directly count the number of sperm per ejaculate rather than use static measures such as testes size or even rely on proxy measures such as ejaculate volume. In short, testes size could increase under sexual selection to produce more ejaculates of the same (or even of a smaller) size, rather than selection to produce both more *and* larger ejaculates. It is inappropriate to use relative testes size to test predictions about ejaculate size, although this is a commonplace inference.

1. Comparative studies

Researchers use the comparative method to investigate the relationship across species or populations between sperm traits and estimates of sperm competition. Species differ greatly in how males allocate resources to traits that increase precopulatory success versus postcopulatory success (Parker et al. 2013). Consequently, it is possible that greater sperm competition might not lead to greater relative testis size if sexual selection strongly favors male investment in precopulatory traits (Lüpold et al. 2014). Therefore, negative phenotypic correlations that are seen within species might not occur at the species-level (Fitzpatrick et al. 2009) or might vary even among related taxa (e.g., Immler and Birkhead 2007).

Comparative analyses across a wide array of taxa show that relative testes size is greater in species that experience higher levels of sperm competition. This is true for estimates of sperm competition based on social group size, rates of extrapair paternity, direct evidence for sneak matings, measures of individual mating rates, female propensity to remate, frequency of sneak males, and so on (Parker 2016). Similar patterns are also seen among populations within a species. For example, relative testes size increases with the level of polyandry in house mice (Firman and Simmons 2008). It has been suggested, however, that a positive relationship between testes size and sperm competition is less likely in invertebrates, especially insects, as more complex sperm storage and the evolution of mechanisms for sperm displacement and removal reduce the importance of the number of sperm inseminated per male in determining paternity (Simmons 2001).

The consistent weakness of all comparative analyses is that while correlations can be detected, causation can only be inferred: experiments are needed to determine causality. Even so, the comparative method has been fruitful. The testis size-sperm competition relationship is sufficiently well established that many studies now use relative testes size as a surrogate measure of the level of sperm competition (Parker and Pizzari 2010; Parker 2016). Even so, some researchers have pointed out there are assumptions, methodological and analytical problems, and potential pitfalls associated with the use of testes size in comparative analyses (Calhim and Birkhead 2007). Ideally, future studies will better distinguish between the sperm producing and non-sperm-producing component of testes, control for ecological factors unrelated to sperm competition that might influence testes size and spermatogenesis, and take into account that sperm production rate can vary per unit mass of testes (Ramm and Schärer 2014; Giannakara et al. 2016).

Comparative studies that directly report on the relationship between ejaculate size (or a proxy thereof other than relative testes size) and level of sperm competition are rare. A comparison of 15 species of *Cataglyphis* desert ants showed that males in species experiencing greater sperm

competition (the number of males that contribute to offspring production by a queen) produce more sperm (after controlling for male size) (Aron et al. 2016). One conceptual issue with such studies is whether testes mass should be controlled. So doing could obscure a relationship between sperm competition and ejaculate size if the main mechanism by which ejaculate size is increased is through the development of larger testes size (as opposed to an increase in sperm production per unit volume of testes).

2. Experimental evolution

Experimental evolution studies of the effects of sperm competition generally involve establishing selection lines in which each successive generation is derived from females that are either forced to mate monogamously (i.e., no sperm competition, cryptic female choice, or sexual conflict) or from females that are allowed to mate with several males (polyandrous). The resultant evolution of male traits after several generations is recorded and any divergence between selection lines, beyond that expected by drift, is attributed to postcopulatory sexual selection and/or removal of sexual conflict over mating rates. Most experimental evolution studies have reported fairly large changes in at least some aspects of ejaculate production. This implies that there is active selection against traits favored by postcopulatory sexual selection in monogamous lines, presumably because such traits are costly. Comparison of monandrous and polyandrous selection lines has, for example, shown the evolution of smaller relative testes size (Gay et al. 2009) and fewer sperm (Firman and Simmons 2011) in monogamous lines.

3. Comparison of mating tactics or social status

Parker (1990; see also: Parker 2016) used game theory models to predict that when there is competition for mates, males in the favored behavioral role, who are less likely to be subject to sperm competition or have an inherent advantage under sperm competition (i.e., there is a loaded raffle), should invest fewer sperm per

ejaculate or have smaller relative testis size than those in the disfavored role (i.e., sneaks). This could lead to permanent differences in investment in ejaculates when males pursue distinct mating or reproductive tactics. Males that consistently pursue a minor strategy (e.g., “sneaker” or “satellite”) always release sperm when another male is present (or has already mated) and therefore have a greater average risk or intensity of sperm competition than those pursuing the major strategy (e.g., a territorial male), who will sometimes mate in the absence of sperm competition. Major males should, therefore, invest more heavily into the production of competitive ejaculates (Parker 1990). A caveat is that the predicted difference depends on the frequency of minors: if they are sufficiently abundant then the risk/intensity of sperm competition experienced is likely to be almost identical for all males. The same argument can be extended from discrete morphs to continuous variation in male social status (e.g., when dominant males are more likely to have exclusive access to females and therefore suffer a lower risk of sperm competition than subordinate males). The use of evidence from morphs or social rank is based on “all else being equal” assumptions about trade-offs between investment into ejaculates and other traits that might not hold. For example, dominant males with access to many females might be at greater risk of sperm depletion and therefore have to trade-off ejaculate size against the total number of matings; or morphs might differ in the fitness returns from investment in traits that increase mating opportunities as opposed to relative fertilization success; or guarder males might invest more heavily in mate guarding to reduce sperm competition than in testes size to increase success under sperm competition; or males that pay a lower cost to obtain a mate (e.g., attractive males) might invest fewer sperm per mating (Parker and Pizzari 2010).

The evolution of differences in sperm expenditure between discrete mating types has mainly been studied in insects and fish, while studies of frogs, birds, and mammals have mainly looked at continuous variation in traits that might affect the extent to which males are in the favored role (Birkhead and Møller 1998; Simmons 2001;

Parker and Pizzari 2010). Simmons et al. (2007b) used *Onthophagus* dung beetles to test the prediction that across species male expenditure on the ejaculate should increase with increasing probability of a sneak mating. Their comparative analysis showed that as predicted smaller, sneaker males (“minors”) have relatively larger testes than guarding males (“majors”) in 14 of 16 species, and in nine species the difference is statistically significant. Many studies on fish show that sneakers have larger relative testes size and/or higher sperm density per ejaculate (Pitnick et al. 2009a). If sperm density is higher then, assuming ejaculate volume is the same, this will lead to larger ejaculate size (defined as total sperm count).

Several studies have examined body condition, body size, or social status as traits that might affect male access to females, hence being in the favored role. For example, in the frog *Crinia georgiana* larger males more often tend to amplex with females during mating, while smaller males tend to be sneakers occupying a more peripheral position. These mating roles are, however, plastic so the same male might find himself in both situations. One study found no difference in relative testes size or ejaculate volume between males captured as guarders or sneakers (Byrne 2004) and a follow-up study confirmed that there was also no difference in ejaculate size between large and small males (Hettyey and Roberts 2007). In contrast, in Arctic charr, subordinate males have larger ejaculates than dominant males (Rudolfson et al. 2006).

4. Phenotypic plasticity in the form of strategic ejaculation

Evidence of phenotypic plasticity in sperm traits in response to variation in known costs and benefits (i.e., costs of producing a different ejaculate weighed against the benefit of the likely number of offspring that will be sired by the focal male) provides the most powerful argument for the extent to which postcopulatory sexual selection favors specific ejaculate traits (Wedell et al. 2002). Selection can sometimes favor facultative or strategic adjustment of ejaculate traits by

males in different mating contexts (delBarco-Trillo 2011; Kelly and Jennions 2011). The key underlying premise of strategic ejaculation is that producing more sperm or generating specific aspects of individual sperm (e.g., tail length) is sufficiently costly that males can profit from adjusting investment into ejaculates depending on the likely net benefits. The secondary premise is, as with all cases of adaptive phenotypic plasticity, that males have informative cues about the costs/benefit of a given level of investment and that the costs of changing their phenotype are sufficiently low to make this worthwhile. The meta-analysis of empirical studies suggests that the rate of return from an ejaculate depends on the number of unfertilized eggs available (e.g., female size) and the risk of sperm competition (Kelly and Jennions 2011). There is less evidence, however, that males allocate fewer sperm when more rivals are present or transfer less sperm when mating with virgin females (Kelly and Jennions 2011).

Is Sperm Quality Sexually Selected?

Although relative sperm number is often the best predictor of a male's fertilization success, even after controlling for mating order effects (i.e., first or last male sperm priority), it still only accounts for a modest proportion of the total variance in success (Snook 2005). If this is not solely attributable to measurement error, then much remains unexplained. One possibility is that certain sperm traits affect fertilization success. There is tremendous variation in sperm morphology and movement among related species, among populations of the same species, and even among males within a population (Pitnick et al. 2009a). Why? One suggestion is that variation in sperm morphology might arise due to cryptic female choice (i.e., male-female interactions and sperm selection), which partly determines males' fertilization success (Pitnick et al. 2009b).

Sperm traits that are potentially under sexual selection when females mate multiply include: sperm viability or longevity; swimming speed/motility; sperm size or length (often measured as

total length, but this can be subdivided into different components such as tail, midpiece, and head length); and sperm type (heteromorphism). These sperm traits (whose expression is sometimes mediated by changes in seminal fluid composition) are often collectively referred to as "sperm quality," which is a measure of fertilization success controlling for sperm number (Birkhead and Møller 1998). The available evidence varies widely for the influence of each trait on ejaculate competitiveness. Here, we consider four main aspects of sperm: longevity, speed, size, and shape/type. As with selection on sperm number, we present evidence that these traits are under selection from: within species studies (i.e., correlations between the focal trait and fertilization success under sperm competition); comparative analyses; experimental evolution (monandry vs. polyandry); comparison of mating types; and studies of adaptive phenotypic plasticity.

1. *Sperm viability or longevity*

Sperm viability is the proportion of live sperm in an ejaculate. Hunter and Birkhead (2002) found that, within seven pairs of closely related species of insect, the species with a higher estimated level of sperm competition tended to have greater sperm viability. Similarly, Fitzpatrick et al. (2009) found that across 29 species of African cichlid fish sperm longevity was greater in species with a higher risk of sperm competition. All else being equal this makes sense as the more sperm that are alive, the greater the likelihood of increased fertilization success relative to a rival. This does, however, imply that there is a cost to increasing longevity. For example, it has been suggested that in external fertilizers (where fertilization occurs shortly after ejaculation) males trade-off reduced sperm longevity against other traits that allow sperm to reach the eggs more rapidly (Pizzari and Parker 2009). It is important to note, however, that the majority of studies investigating the effect of sperm quality on fitness are correlational. Thus, sperm longevity, for example, might always have the same functional effect, but be obscured by variation in other sperm/ejaculate traits that effect fertilization

success, but do so differently across species (e.g., sperm size is probably more important in some species than others), and that affect resource allocation to sperm longevity. Unfortunately, the challenge of experimentally manipulating individual sperm traits is enormous. Causality therefore has to be inferred based on correlations and other indirect types of evidence.

Sperm viability and longevity appear to be phenotypically plastic traits that males can adjust in response to social changes that should affect sperm competition levels. For example, in *T. oceanicus*, sperm viability is a good predictor of a male's relative fertilization success (Garcia-Gonzalez and Simmons 2005). Males produced ejaculates with an intermediate level of sperm viability when mated to virgin females, higher sperm viability when mated to a once mated female, and far lower sperm viability when mated to an already multiply-mated female (Thomas and Simmons 2007). This variation in sperm viability is assumed to be a response to male assessment of how many times a female has already mated based on chemical cues left by previous males. In addition, there is evidence that males adjust sperm viability based on cues about the future level of sperm competition, such as the number of rival males they encounter before mating (Simmons et al. 2007a).

2. Sperm swimming speed and motility

One might predict that sexual selection favors fast swimming sperm that reach unfertilized eggs before the sperm of rivals (Pizzari and Parker 2009). In practice, predictions about the association between sperm swimming speed and sperm competition are complicated by potential trade-offs with longevity and/or size that can also be under selection, although the nature of any such trade-offs remains uncertain (Pizzari and Parker 2009). If fertilization is delayed (e.g., due to sperm storage in internal fertilizers), then selection might actually favor slower sperm (if this increases survival time in the female reproductive tract) or faster sperm (to more rapidly reach female sperm storage organs where survival rates are higher). In external fertilizers, however,

it is generally assumed that swimming speed is more important than longevity.

In a comparative analyses of 29 African cichlid fish there is evidence that species with a higher level of sperm competition have faster swimming sperm (Fitzpatrick et al. 2009); the same was true in a study looking at 42 temperate passerine bird species (Kleven et al. 2009). However, another bird study found no relationship between swimming speed and level of sperm competition across 40 species, although sperm length was positively correlated with both traits (Lüpold et al. 2009). The evidence from within-species studies is also ambiguous. A few studies in birds and fish have shown that relative fertilization success is positively related to greater sperm motility within species (Pizzari and Parker 2009). Meanwhile, slower swimming speed and a higher proportion of motile sperm increase relative fertilization success in the myobatrachid frog *Crinia georgiana* (Dziminski et al. 2009). At present, the general relationship within species between sperm speed or motility and fertilization success remains uncertain. Another line of evidence is to look for differences in sperm traits between discrete mating types in fishes (e.g., sneakers and territorial males). These data provide some evidence that sperm motility and/or velocity are under selection. Sneaker males, who tend to experience more intense sperm competition than territorial males, tend to have faster swimming or more motile sperm than males using other reproductive tactics, but the relationship is weak (Pitnick et al. 2009a).

There are very few studies that test whether sperm motility or velocity are phenotypically plastic traits that males adjust in response to social changes that affect the level of sperm competition. In humans, sperm motility increased when men were exposed to images suggestive of greater sperm competition (Kilgallon and Simmons 2005); but we need more studies that experimentally manipulate variables associated with greater sperm competition levels (e.g., population density, lower social status) to see if and when this leads to the production of more motile sperm. Ideally researchers should directly measure sperm speed rather than infer it from other traits because we still do not know what properties of a

sperm increase its swimming speed (e.g., the optimal ratio of head to midpiece to tail length) (Simpson et al. 2014).

3. *Sperm length or size*

The number of sperm in an ejaculate is usually several orders of magnitude greater than the available number of unfertilized eggs. This presumably reflects strong sexual selection under sperm competition for greater numerical representation of sperm (Gage and Morrow 2003). Given a fixed investment into each ejaculate, it is therefore predicted that sperm will be tiny because of a trade-off between size and number (Pizzari and Parker 2009). If relative sperm number is the major predictor of male fertilization success under sperm competition then any gains from greater sperm size (e.g., higher zygote survival due a greater male parental investment) are likely to be outweighed by the decline in the total number of eggs fertilized. Intriguingly, however, evidence for a size-number trade-off from comparative studies across species or population or even from within-species correlations is ambiguous (Snook 2005; Pizzari and Parker 2009). This is not really surprising though as confounding variables (e.g., variation in total resources among males when looking at within species patterns) can easily obscure genuine causal relationships between traits, such as a resource trade-off (Reznick et al. 2000). Although there are very restrictive conditions under which larger sperm size might be under natural selection for fertilization efficiency (Snook 2005; Pizzari and Parker 2009), it is more plausible that sexual selection favors greater sperm size. For example, larger sperm might be better able to displace rival sperm, or avoid being displaced from female sperm storage organs, thereby increasing a male's numerical representation of sperm at the time of fertilization. This could lead to coevolution of sperm size and the dimensions of female sperm storage organs (Pitnick et al. 2009b).

In many cases, it is assumed that sperm size is indirectly favored because it has a functional effect on other traits that are the target of sexual selection. For example, selection might favor

faster-swimming sperm, which can be achieved by an increase in sperm size (Snook 2005; Pizzari and Parker 2009). Similarly, larger sperm might be indirectly selected for if this increases longevity, and longevity elevates fertilization success when there is a delay between insemination and fertilization (Snook 2005; Pizzari and Parker 2009). Correlational studies have shown, however, that a size-longevity relationship can be positive, negative, or absent (Snook 2005; Pizzari and Parker 2009). Alternatively, even smaller than usual sperm might be favored if fertilization occurs shortly after ejaculation so that longevity has less effect on male fitness than the number of sperm released. Consequently, current models predict sexual selection for either longer or shorter sperm depending on: the fertilization mode (e.g., external vs. internal fertilization); delay between insemination and mating; how sperm size affects longevity or swimming speed; whether female-sperm interactions favor larger or smaller sperm; and the extent to which the number of competing sperm affects the competitiveness of different sized sperm (Snook 2005; Pizzari and Parker 2009).

The relationship between sperm length and relative fertilization success varies widely across species from significantly positive to negative. It is worth noting that stronger postcopulatory sexual selection is associated with reduced variation within and among males in sperm length, suggesting stronger stabilizing selection on sperm size (Pizzari and Parker 2009). Interestingly, this conflicts with the general view that secondary sexual traits show higher variation among males than other traits, a pattern which is usually attributed to condition-dependent expression. The implication is therefore that sperm quality traits are less often condition-dependent, although the available evidence is ambiguous (Lüpold et al. 2016).

In experimental evolution studies, the elimination of sperm competition through enforced monandry does not generally lead to the predicted evolution of shorter (less costly) sperm (Pitnick et al. 2009a), although it did lead to a significant decrease in sperm size in at least one hermaphrodite species with high and low rates of selfing (LaMunyon and Ward 2002).

Strategic ejaculation of different sized sperm in response to a change in the likelihood of sperm competition has, to our knowledge, been reported once only. In the ascidian *S. plicata*, experimental manipulation of adult densities (presumably increasing sperm competition levels) resulted in the production of larger sperm at higher adult densities (Crean and Marshall 2008). This is opposite to the predicted response given a size-number trade-off (Parker 1998; Pizzari and Parker 2009). One suggestion is that the result reflects selection to reduce polyspermy (zygote failure because too many sperm enter the egg), which occurs in some broadcast spawners, such as *S. plicata*. However, reduced sperm production would only be selected for if polyspermy arises partly due to multiple sperm from the same male entering a given egg (otherwise males that produce fewer sperm would increase the relative success of other males at a cost to their own chances of fertilizing fewer eggs).

More generally, there is evidence that environmental factors affect sperm size. For example, sperm length increases at higher temperatures and decreases with greater larval density (Pitnick et al. 2009a). There is, however, little evidence that diet affects sperm size. To date, none of these environmental factors (with the possible exception of larval density) have been shown to predict the future level of sperm competition. Nonetheless, these studies suggest that phenotypic plasticity in sperm size is at least possible, albeit that this is probably due to longer-term developmental changes in males rather than the rapid changes in sperm production mechanisms. Perhaps the best evidence that strategic ejaculation of different sized sperm is possible comes from studies showing a difference in sperm size between successive ejaculates from the same male, which might be related to the risk of sperm competition (Pitnick et al. 2009a).

Comparisons of mating types provide weak support for the claim that sperm size is under strong sexual selection. Studies comparing sperm length between males using different mating tactics reveal no differences in several species of fish and insects (Snook 2005).

4. Sperm type

The most extreme within-species variation in sperm types occurs when males produce both fertile (eusperm) and infertile sperm (parasperm). The later are often considerably shorter than the former. Parasperm have been intensively studied in Lepidoptera, but discrete sperm types have been reported in many other taxa, ranging from rotifers to fish (Pitnick et al. 2009a). A variety of hypotheses for the existence of discrete sperm types have been formulated (Pizzari and Parker 2009). Some of these explanations invoke natural selection for improved fertilization rates or that infertile sperm are simply a way to transfer nutrients to females that are a form of male parental investment. However, many explanations assume that sexual selection favors the division of labor between distinct sperm types to increase ejaculate competitiveness (either offensive or defensive). Unfortunately, experimental tests of these hypotheses are largely lacking (Pitnick et al. 2009a). Some studies have, however, begun to elucidate how parasperm and eusperm interact to increase fertilization success (Pitnick et al. 2009a).

Some of the most convincing evidence that parasperm evolved under sexual selection comes from studies testing for facultative adjustment in the proportion of parasperm in ejaculates in response to the level of sperm competition. For example, male moths (*P. interpunctella*) transfer more eupyrene but not more apyrene sperm to mated females (i.e., when sperm competition is inevitable) (Cook and Gage 1995). Long-term studies – that might reflect developmental shifts rather than short-term strategic ejaculation – also show that the snail *Viviparus ater* increases the proportion of non-fertilizing, oligopyrene sperm when the sex ratio is male-biased so that the risk of sperm competition is higher (Oppliger et al. 1998).

Conclusion

Our focus here has been on sperm competition in nonhuman animals. We have highlighted several

intriguing and exciting discoveries in sperm competition research while also highlighting many of its associated problems and pitfalls. Importantly, these problems arise in studies using simple animal model systems in experimentally controlled situations. We therefore urge caution to those studying sperm competition in humans; it is imperative that investigators carefully consider how hypotheses are tested, how variables are measured, and how results are interpreted.

Sperm Competition: Evidence in Nonhumans

Institute of Vertebrate Biology, Czech Academy of Sciences, Brno, Czech Republic

Faculty of Science, Charles University, Prague, Czech Republic

Synonyms

Post-copulatory Sexual Selection; Sexual promiscuity; Sperm competition

Definition

Sperm competition arises when the sperm of two or more males compete to fertilize a given set of ova. This broad definition includes both competition between sperm of two or more males within the body of a single female (internal fertilizers) and processes observed when fertilization takes place outside the female body (external fertilizers), as in most bony fishes or amphibians

(Parker 1998). It is worth noting that, in a broader sense, gamete competition occurs in most sexually reproducing organisms. In plants, for example, pollen (male gametes) of several individuals may compete to fertilize the same set of female gametes which, in principle, follows the classic sperm competition scenario described in animals (Delph and Havens 1998).

Introduction

The term “sperm competition” was first defined by Geoffrey Parker based on his seminal work on mating strategies in *Scatophaga* flies (Parker 1970). He realized that mate choice and sexual selection continue long after copulation in this insect, which led to our present understanding of postcopulatory sexual selection processes by revealing the – until then hidden – components of variation in male reproductive fitness. The evidence for sperm competition has been accumulating ever since. Not only have follow-up studies identified extraordinary variation in the levels of sperm competition among species, they have also uncovered a plethora of behavioral, morphological, physiological, and molecular adaptations that have evolved in males and females in response to sperm competition. In males, such adaptations could include differences in ejaculate load and sperm size or shape (Pizzari and Parker 2009), while various sperm storage organs may evolve in polyandric females to facilitate sperm competition and choice of the most viable sperm. Moreover, postcopulatory sexual selection, including sperm competition, has been identified as potential mechanism leading to the emergence of prezygotic barriers to gene flow between populations, and hence speciation (e.g., Howard et al. 2009). Mechanisms of sperm competition could involve male precedence or displacement, where the sperm’s ability to outcompete the sperm of other males depends on the order in which males mate with a given female, or could simply depend on the amount of ejaculate (sperm number) from each male, that is, a fair-raffle scenario with “more tickets in the raffle” being the winner (reviewed in Parker 1998).

As mentioned above, there is tremendous variation in the level of sperm competition across species, and even across populations of the same species. Approaches to studying levels of sperm competition include analysis of unexpected segregation of paternal heritable traits in offspring, behavioral observations and deviance in estimated heritability between paternal and maternal genotypes (e.g., Griffith et al. 2002). In addition, phenotypic traits known to evolve in response to varying levels of sperm competition (usually relative testis mass) may be used as surrogates for levels of sperm competition in given species or populations (Soulsbury 2010). In recent years, however, sperm competition levels have typically been estimated via molecular analysis of paternity. Paternity analysis, which uses the DNA of offspring to identify the number of putative genetic fathers, only became possible due to rapid progress in molecular testing over the last two decades of the twentieth century, the so-called parenting revolution. Below, I provide an overview of sperm competition, based on a range of more-or-less direct sources of evidence, and its evolutionary consequences across the animal kingdom, focusing on well-known model systems.

Sperm Competition in Invertebrates

In invertebrates, evidence for sperm competition has been accumulating since the 1970s (Parker 1970). Interestingly, in some invertebrate groups, such as some corals, flatworms, and sea slugs, sex roles are not well defined. Typically, these organisms are simultaneous hermaphrodites, with male and female gonads occurring in each individual. Alternating the role of sperm exchange is relatively common in this system and insemination is reciprocal. Donors provide sperm and receivers ova; however, mating conflicts often arise concerning an individual's role (donor or receiver) due to advantages gained by being the sperm donor (Michiels 1998). Given the low population density of most hermaphrodites, there is only limited space for sperm competition to occur. Some species, however, are able to "mate multiply." In sea slugs and some flatworm species, for example,

autosperm (own sperm) are donated to one partner and allosperm received from another partner. In the nematode *Caenorhabditis elegans*, while hermaphrodites typically use their own sperm for fertilization (selfing), the sperm of rarely occurring males outcompete the hermaphrodite's own sperm.

Control over mating leads to some bizarre adaptations. In *Macrostomum* flatworms, who practice reciprocal mating, bristles have evolved on the sperm's surface, ensuring that sperm are not ejected and are utilized by a reciprocally copulating partner. On the other hand, where there is no "female" control over the fate of ejaculated sperm, such as when mating occurs via hypodermic (traumatic) insemination, the sperm lack bristles and are small and highly motile (Schärer et al. 2011). In the latter case, more donors tend to provide sperm, which compete over fertilization within the body of the recipient, another example of fair-raffle sperm competition favoring small and more numerous spermatozoa.

Molluscs provide some notable examples of hermaphroditism. In this group, several types of sperm are sometimes produced by a single individual. While eupyrene sperm carry DNA and are responsible for fertilization of the ova, the role of apyrene or oligopyrene sperm remains less clear, though they may play a role during sperm competition. The occurrence of sperm storage organs indicates that sperm competition could be common in this group (Baur 1998). Evidence for multiple paternity exists in mussels, though examples of parentage analysis are rare. Gonochorism, with individuals having just male or female reproductive organs, is typical in Cephalopods. Both sperm storage and mate guarding occur in this group and most cephalopod species analyzed to date appear to mate multiply. In dumpling squid *Euprymna tasmanica*, for example, all clutches laid naturally had multiple paternity, with 2–4 males siring the clutch. Females of this species store sperm for extended periods, multiple paternity resulting from females mating between layings with different partners (Squires et al. 2013). "Last sperm precedence" appears to occur in squid, whereby the later copulating male sires a disproportional number of offspring.

Spiders and other Arachnida serve as a popular model group for sexual selection (reviewed in Elgar 1998). Interestingly, there appears to be evidence for first male precedence in some spider species, while last male sperm precedence clearly occurs in other arachnids. Several adaptations that have evolved in spiders would appear congruent with the existence of sperm competition in this group. Male spiders, for example, may transfer substances in the seminal fluid that interfere with female receptivity, or plug females with secretions or genital (pedipalps) fragments, making the female less accessible to subsequent males. In some spider species, females possess paired sperm storage organs (spermathecae), facilitating separate sperm storage from different males.

Insects are among the most intensely studied group as regards sperm competition and post-copulatory selection mechanisms, including the original work on *Scatophaga* flies (Parker 1970) that defined the term “sperm competition.” As in other arthropods, sperm storage organs have also evolved in insects. Moreover, most insect females will accept copulation with another male before the stored sperm are exhausted. Hence, a temporal and spatial overlap of sperm from different males often occurs within the female sperm storage organs, providing opportunities for sperm competition. Indeed, a plethora of adaptations appears to have evolved in insects in response to sperm competition. Males of some species deliver their sperm in “spermatodoses” that may overlay the sperm of other males in the female spermatheca. “Sperm displacement” could be achieved by flushing female sperm-storage organs with their own ejaculate, thus effectively removing spermatozoa of competing males. The penises of some beetles and Odonates have adaptations for removing sperm from the female spermatheca (Simmons and Siva-Jothy 1998). Mating plugs have also evolved in some insect species to prevent other males from removing the preceding male’s sperm. In general, mixed sperm utilization (including fair-affle scenarios) and second male precedence are the most common patterns of sperm utilization observed in insects (reviewed in Simmons and Siva-Jothy 1998). In just a few species, males

and females form pair associations during the reproductive season and exhibit biparental care. Males of these species tend to copulate with their partners frequently in order to avoid the risk of sperm competition. Despite this, multiple female mating remains common. For example, in the horned passalus *Odontotaenius disjunctus*, a socially monogamous beetle exhibiting biparental care, 54% of offspring in 70% of nests are sired by extra-pair males (Dillard 2016).

Sperm competition appears to be associated with ejaculate properties in insects, such that males of polyandrous species (where females mate with multiple males) have more viable sperm than males of monandrous species (Hunter and Birkhead 2002). In the same vein, within- and between-male variation in sperm length appears to be reduced in polyandrous species, indicating that stabilizing selection on sperm length occurs in species where females store spermatozoa in specialized organs after copulation (e.g., see discussion below concerning birds). In several insect species, larger sperm outcompete smaller rival sperm, possibly through enhanced displacement. This may lead to the evolution of very large sperm in some insects, a notable example being fruit flies of the genus *Drosophila*, in which more promiscuous species produce longer sperm and males generally produce just a few truly gigantic sperm. In *Drosophila bifurca*, a small fly with body length of less than 3 mm, sperm can be up to 5.8 cm long, 1000 times longer than a human sperm and by far the longest sperm on Earth! Sperm size in fruit flies can be considered a classic Fisherian trait (somewhat like a peacock’s tail), evolving through runaway coevolution between length of sperm and the size of the female’s receptive organs (Lüpold et al. 2016). Several *Drosophila* species have evolved a process known as “traumatic insemination.” This unusual method of male-female interaction, whereby the male pierces female abdomen and injects sperm directly into her abdominal cavity, has also been detected in several other unrelated insect groups such as bed bugs (*Cimex*), where it may have evolved as a result of sexual conflict for control of insemination (see Tatarnic et al. 2014 for further discussion).

Sperm Competition in Vertebrates

Both internal and external modes of fertilization occur in vertebrates and evidence of sperm competition is apparent in both. Most fishlike vertebrates and amphibians are external fertilizers, with sperm reaching the ova outside the female; indeed, this process is typical for aquatic species. In most fishes, external fertilization provides an opportunity for ova to be fertilized by multiple males simultaneously (reviewed in Petersen and Warner 1998) as several males may release sperm during the spawning event. Many species even display parasitic spawning. External fertilization in fishes may encourage subordinate males to adopt an alternative reproductive tactic such as sneaking during mating. Sneaker males tend to be smaller and less conspicuous than dominant androgynous males and may “steal” fertilizations from dominant males during spawning. The presence of male sneakers may be beneficial to females, indeed females often fail to show sneaker avoidance (reviewed in Reichard et al. 2007). Even in fish species where fertilization is internal and offspring are carried in body cavities, the proportion of broods sired by multiple males can reach up to 100% (reviewed in Coleman and Jones 2011). In contrast, multiple paternity is absent in fish species such as seahorses (*Hippocampus*) where male pregnancy occurs. Sperm competition is also less intense in species where males build and defend nests (Coleman and Jones 2011). Sharks and other Elasmobranchs are strictly internal fertilizers, the ova being fertilized within the female reproductive organs. Although their reproductive biology is still poorly known, recent studies have confirmed that multiple paternity, and hence sperm competition, is common in several shark species (reviewed in Fitzpatrick et al. 2012).

Evidence for sperm competition has also been documented in various amphibians fertilizing internally and externally. In some internally fertilizing salamanders, females store sperm for a prolonged period, opening space for the sperm of several males to compete within the female body. In red-backed salamanders *Plethodon cinereus*, a terrestrial and socially monogamous

species, over 80% of clutches are sired by more than one male (Liebold et al. 2006). Likewise, sperm competition is intense in externally fertilizing frogs and toads, in which the clutches of single females also display multiple paternity (e.g., Laurila and Seppä 1998). Unlike fish, simultaneous sperm release is uncommon in frogs and toads.

Living amniotes include the sauropsids (reptiles and birds) and synapsids (mammals), all of which are internal fertilizers. Regarding sperm competition, the major focus has been on birds and mammals, while reptiles remain somewhat neglected. This has now changed, however, and recent estimates in reptiles suggest multiple paternity occurs in over 50% of clutches (reviewed in Uller and Olsson 2008). Sperm competition in reptiles can arise through females mating with more than one male during a single reproductive cycle in combination with the ability to store sperm from several males over several reproductive cycles (up to several months in some species). Sperm storage organs in reptiles appear to be less differentiated than in arthropods but still allow for long-term sperm storage. In general, turtles appear to have lower levels of multiple paternity than lizards and other squamates. The proportion of clutches with multiple paternity varies considerably among reptiles, ranging from genetic monandry (as in leatherback turtles *Dermochelys coriacea*) to complete genetic polyandry (some snakes), with 100% of clutches containing multiple paternity. Multiple paternity, with over 30% of clutches sired by more than one male, also occurs in crocodiles, the closest living relatives of birds.

From the very beginning, birds have been at the center of paternity-oriented research (Griffith et al. 2002), possibly as their social systems resemble those of humans (i.e., the prevalence of social monogamy). This despite the fact that levels of sperm competition could actually be higher in some other vertebrate groups, such as reptiles, bony fish, or mammals (Coleman and Jones 2011). Since the late 1980s, more than 30,000 offspring of around 200 avian species have been screened for paternity status. As in some reptiles, female birds are capable of storing sperm over time in specialized organs known as

“sperm storage tubules” (SSTs), situated at the uterovaginal joint. For a given species, SSTs will typically be three times longer than the sperm cell, indicating intimate coevolution between sperm length and female sperm storage organ (Birkhead 1998). Interestingly, as the sperm of different males must find space when fitting into the SST, balancing selection on sperm size should be stronger in species with a high risk of sperm competition. Indeed, as in some insects, sperm length variation between males in polyandrous (promiscuous) species is reduced compared to species with relaxed sperm competition (Kleven et al. 2008).

Levels of sperm competition in birds are typically inferred based on paternity studies. Given that social monogamy prevails, multiple paternity in birds is often termed “extra-pair paternity” (EPP). Up to 80% of all offspring in some small passerines (e.g., Australian fairy-wrens [*Malurus*]) may display EPP. On the other hand, EPP is almost absent in 10% of avian species, particularly in large-bodied and long-lived species with substantial male contribution to parental care, such as owls, birds-of-prey, and seabirds. EPP affects around 19% of broods in socially monogamous species, with around 11% of offspring resulting from EPP (Griffith et al. 2002). As in other taxa, the ejaculate of highly promiscuous species (such as the polygynous Galliformes) is selected for high quality, whereas the ejaculate of genetically monogamous species with relaxed or absent sperm competition (such as owls, falcons, or penguins) often contains a large proportion of abnormal or immature sperm. Moreover, the ejaculate of promiscuous species will contain longer and faster sperm cells. Mate guarding and frequent within-pair copulations to ensure control over paternity are also typical of promiscuous avian species (Birkhead 1998). Moreover, differential sperm allocation has been demonstrated in some bird species. In the jungle fowl (*Gallus gallus*), for example, cocks allocate sperm supplies differentially based on female quality, her level of polyandry, the number of partners available and the male’s own perceived quality (e.g., Cornwallis and Birkhead 2007).

Sperm competition is widespread in mammals, including primates, with some 35% of litters containing offspring sired by more than one male. In fact, multiple paternity levels seem to be higher in mammals than in birds (Coleman and Jones 2011) but may vary in space and time. To date, no genetic polyandry has been detected in only few mammalian species (reviewed in Huck et al. 2014). Relative testes mass, which has traditionally been used as a proxy for sperm competition levels in mammals (reviewed in Soulsbury 2010), tends to be greater in spontaneously ovulating species than those where males induce ovulation (i.e., ovulation is triggered by copulation), such as some cats, hares, and rodents. Spontaneous ovulators also tend to have higher sperm concentrations and produce ejaculates with a greater number of sperm, which is in line with the hypothesis that intense sperm competition selects for more competitive ejaculate across species. As in other groups, mammalian sperm morphology is clearly shaped by postcopulatory processes, with some exceptional examples. In the muricid rodents (Muroidea), for example, hooks have evolved on the sperm head as a response to intense sperm competition. Sperm cells use these hooks to form groups sometimes comprising hundreds or even thousands of sperm cells, commonly known as “sperm trains.” These “trains” move faster within the female reproductive tract than single sperms, thus allowing the sperm to reach the ova before that of other males. An important prerequisite for this unusual form of cooperation is that the sperm cells of particular males recognize each other and avoid forming trains with genetically unrelated sperm (Fisher and Hoekstra 2010).

In four marsupial species, “suicidal reproduction” (semelparity) has evolved in response to sperm competition. In such cases, an extreme burst of steroid hormones facilitates male investment into sperm production and ejaculate quality. Excessively high testosterone levels lead to the collapse of the immune system, however, and reproducing males die very soon after the mating season (Fisher et al. 2013). As males typically live for only 1 year, even without breeding, they are unlikely to mate in the following season; hence,

such a lethal investment into ejaculate quality is adaptive. It has also been shown experimentally that sperm competition in these marsupials enables females to improve offspring survival and own lifetime fitness by mating promiscuously. Though rare, this system provides a clear example of indirect benefits gained by promiscuous females from polyandry.

Conclusion

There is now solid evidence that multiple paternity is common in animals. Indeed, today, genetic monogamy is only rarely detected in paternity studies (e.g., Huck et al. 2014). It should be noted, however, that while the presence of multiple paternity indicates that sperm competition occurs, its absence is no proof that sperm competition is absent (Parker 1998). How then does female reproductive promiscuity evolve and how is it maintained? Traditionally, adaptive explanations for female promiscuity have suggested that females gain direct (material) or indirect benefits in terms of improved genetic diversity or genetic quality of offspring by mating with multiple males. Social aspects, including avoidance of infanticide by mating with multiple males, should also be considered, particularly for some taxonomic groups. Unfortunately, the indirect benefits resulting from female promiscuity are difficult to study. In birds, for example, there is no clear consensus as to whether sexual promiscuity is adaptive and beneficial to females (Forstmeier et al. 2014). On the other hand, the existence of sexual promiscuity could result in costs to females, such as sexual harassment from males, forced copulations, or disease transfer. Some of these costs also apply to males, yet mating with multiple mates appears to have an obvious net positive effect on male fitness (Trivers 1972).

We are far from resolving the enigma of genetic polyandry in animal populations and its evolutionary significance. Interestingly, one recent study has indicated that extinction risk following a genetic bottleneck is lower in promiscuous populations (Lumley et al. 2015), implying that, under certain circumstances, sexual promiscuity may be an important mechanism of mate

choice with similar effects on population genetic quality as those proposed for the sexual mode of reproduction itself.

Definition

Female sperm storage is a biological process where sperm is temporarily retained within a specific part of the female reproductive tract before the oocyte, or egg, is fertilized.

Introduction

Female sperm storage often occurs when sperm cells are transferred into a female during mating. This form of sexual selection has evolved to ensure that conception occurs at different times and/or in different environments. Sperm storage is an essential step in reproduction and is often required for successful fertilization.

Sperm

On average a male can produce 1500 sperm per second (Baker and Bellis 1993). The average male can ejaculate anywhere from 280 to 500 million sperm per ejaculation (Moore et al. 2015). The chances of fertilization appear high; however, there are many obstacles sperm encounters during the process of conception. The underlying evolutionary processes affecting successful male fertility are determined by the sperm's ability to survive within the female reproductive tract.

Variables Necessary for Survival

Individual longevity of sperm and the internal metabolic capacity of sperm are essential for survival. The anatomy of sperm influences the survival and probability of fertilization. A sperm's speed and length play an imperative role in sperm competition. The tail of the sperm helps propel them toward the cervix and into the fallopian tube to wait for egg fertilization. Semen or seminal fluid is the nourishing fluid that surrounds and protects the sperm before entering the cervix (Moore et al. 2015). Seminal fluid is necessary for sperm survival; without semen, sperm would have a zero probability of conception. The environment of the vagina including body temperature, pH levels, and relative acidity determines the survival and storage of sperm (2015). The components in seminal fluid counterbalance the acidic environment of the vagina.

Fertile cervical fluid is essential for sperm to survive and necessary for conception. The presence, quantity, and quality of female cervical mucus affect the internal metabolic capacity

of sperm (Wilcox et al. 1995). Since the vaginal environment is typically highly acidic, the presence of fertile cervical fluid is necessary for conception. Cervical fluid allows the sperm to easily swim into the cervix. Without fertile cervical mucus, the sperm would rapidly die and the potential success of conception reduces to a few hours during the peak of ovulation (Wilcox et al. 1995).

Once the sperm reaches the fallopian tube, the sperm awaits the opportunity to fertilize an egg. Sperm can potentially survive for up to 5 days in the female reproductive tract (Wilcox et al. 1995). Only a minimal number of sperm will even survive the long journey through the female reproductive tract.

The evolution of female sperm storage ensures high rates of fertilization and mating success within the reproduction of the human species. This type of natural selection assists in the fertilization and conception of mammals faced with a plethora of deterrents.

The Penis as a Sperm Displacement Device

If a female's egg comes into contact with male A's sperm, male B can still fertilize that same egg within up to 5 days, depending on the female's cervical fluid acidity. There is a growing body of literature showing the human penis as a way to remove existing sperm from the female's vagina, to interrupt the storage of another male's sperm. Recent work has shown a replication of this hypothesis, with artificial penises, vaginas, and sperm showing a similar effect. This behavior is seen not only in humans, but in animals as well, even in birds such as chickens, perhaps giving us a greater understanding how the penis came to be shaped evolutionarily (Gallup et al. 2003).

Conclusion

In conclusion, female sperm storage is an essential means of eventual fertilization. Fertilization, therefore, is a key component of evolution, as the only way any species can continue is through survival and reproduction.

Spiritualism

Demetra Themistocleous and Xenia Anastassiou-Hadjicharalambous
University of Nicosia, Nicosia, Cyprus

Synonyms

[After life](#); [Beliefs](#); [Spiritism](#); [Spirits](#)

Definition

Spiritualism is a belief that the deceased souls have the ability to communicate with the living with the help of a medium.

Introduction

Spiritualism propagates that the souls of the dead have both the capacity and the tendency to interact with the living. Spiritualists believe that spirits continue to evolve in the spirits world. Since they can communicate with the deceased souls and they considered the spirits superior than humans, they believe that spirits can give us the information and the knowledge about ethical issues, as well as to answer any questions related to God. Many spiritualists seek spiritual guidance to help them with their personal growth in life (Carroll 1997; Braude 2001). Kardec (1996) proposed spiritism, in which he emphasized the process of reincarnation.

The first case reported of a living to communicate with a spirit was in 1848. The Fox sisters, Margaret and Kate, moved with their family to a cottage, until their house was built in a nearby land. Since the first days they moved in the cottage, the whole family was listening to bizarre noises, with the two girls reporting the presence of unusual voices and movements. One day, while their father was searching the house to find out from where all these noises are coming from, Kate observed that when her father knocked a wall or a door, there was a reply. So she realized that someone was trying to communicate with them. Soon after, the Fox sisters became popular for their mediumistic powers and they were giving performances of their gift. The news of their supernatural communication with the spirits spread in the world and the movement of spiritualism commenced (The haunted museum n.d.). The notion of spiritualism developed for many years through magazines, preaching, and tours by highly skilled mediums. With respect to evolution, both evolutionary theories as well as spiritualism believe in the gradual progression of society. Yet, the postulation that the humans derive from the animals has been viewed by Spiritualists as threatening to the belief of immortality of the mankind. Spiritualists' view of evolution is that life does not stop with death. It goes beyond death in new spheres of spiritual existence. According to Spiritualists, Darwin's evolutionary theory does not adequately explain human evolution. It has been postulated that Darwin's theory only partly explains human evolution, and Spiritualism fills in this gap, since even if the origins of the mankind could derive from animal creation, still the inherent cause of the development is Spiritual.

Conclusion

Spiritualism is a movement in which the spiritualists communicate with the spirits of dead people with the help of mediums. Its believers argue that by interacting with the spirits, they could establish the validity of a person's survival after their demise. Today, although there are some people who believe in life after death, it is not quite widespread.

[Callosotomized patients](#); [Callosotomy patients](#)

Definition

The expression "split-brain" was first used in the 1960s by Roger W. Sperry of the California

Institute of Technology (Sperry 1961), referring to those animals who had undergone the surgical resection of the *corpus callosum* (CC), the largest nerve bundle connecting the left and right cerebral hemispheres (the surgery is called callosotomy). In some cases, the expression is specifically used to refer to the resection of all of the cortical commissures (commissurotomy; here both callosotomy and commissurotomy are used without further distinctions; for a deeper differentiation, see Corballis 1995). Thus, the expression “split-brain patients” is used to refer to such patients who usually suffer a very disabling form of epilepsy which does not respond to pharmacological treatment, so much so that the surgical resection of the callosal fibers is performed to prevent the spreading of seizures across the two sides of the brain. Sometimes, the callosal fibers are sectioned in the presence of a brain tumor. The hemispheric disconnection can be complete (involving all of the callosal portions) or partial (involving only a portion of the CC; Fig. 1). A difference has to be underlined between split-brain patients, who receive the surgical resection of the CC, and acallosal patients, in whom the callosal fibers are absent from birth.

Introduction

The first callosal resections in humans were performed in 1940, in a group of 26 epileptic patients at the University of Rochester, by the neurosurgeon William P. Van Wagenen. Tested by the neurologist Andrew J. Akelaitis, these patients showed a decrease in epileptic activity, but Akelaitis did not notice marked behavioral or cognitive disorders as a consequence of the surgery.

A different frame emerged, however, from the commissurotomies performed on monkeys, rats, and cats in the 1970s at Caltech (California Institute of Technology), revealing that the resection of the interhemispheric fibers prevented the information exchange between the left and the right side of the animals' brain. In those years, Philip J. Vogel and Joseph Bogen were successful in reducing the epileptic activity of a man by

means of commissurotomy, starting from the assumption that only a complete interhemispheric surgery disconnecting all the cortical commissures would interrupt the epileptic propagation. In fact, besides the CC, other minor commissures in the human brain exist, such as the anterior commissure, the hippocampal commissure, the posterior commissure, and the intercollicular commissure.

In this context, Michael S. Gazzaniga started his research on the “Caltech patients”, working in Sperry's lab (see Gazzaniga 2015). In this same lab, Ron Myers had noticed some behavioral abnormality in split-brain animals (e.g., after the surgery, the monkey's hands seemed to become independent from one another), and Gazzaniga was interested in assessing whether a callosal disconnection would truly lead to a lack of behavioral and cognitive effects in humans. Under the supervision of Sperry, Gazzaniga performed a large number of experiments aimed at answering this question, and the results of those experiments represent a milestone of the cognitive neurosciences even today. Indeed, those works revealed effects of hemispheric imbalance that were completely unknown, to the point that in 1981, Sperry was awarded the Nobel Prize in Physiology or Medicine for the discoveries on the functional specialization of the cerebral hemispheres. From then on, the “split-brain literature” would reveal the coexistence of two minds in a single brain.

Hemispheric Asymmetry and the Divided Brain

The assumption at the basis of the split-brain studies is the crossed organization of the human sensory and motor systems, meaning that (i) stimuli presented to the left side of the body are directly projected to the right hemisphere and vice versa (Fig. 2) and (ii) motor commands from the right hemisphere directly control the left half of the body, and vice versa. Once a stimulus reaches the contralateral hemisphere, the cortical commissures ensure that the information also reaches the hemisphere ipsilateral to the stimulus (e.g., left eye: left hemisphere), by means of an

D.D.V.'s brain, showing the complete absence of callosal fibers; on the right, A.P.'s brain, showing a callosal section saving the splenium

indirect pathway involving the CC. In the split-brain patients, this latter pathway is abolished, due to the resection of the callosal (or commissural) fibers, and thus only the contralateral hemisphere receives sensory information. Due to this peculiarity of brain organization, in humans the response of each disconnected hemisphere can be investigated by using some special artifices.

One of the most exploited paradigms for the investigation of visual asymmetries is the divided visual field paradigm, i.e., the very rapid (tachistoscopic) presentation of a visual stimulus in a single visual hemifield. Starting from the direct contralateral projections of the visual pathways, a left-hemispheric dominance for linguistic processing has been largely shown in the healthy

population, confirmed by rich evidence in neurological patients with unilateral lesions. This left-hemispheric superiority for linguistic processing was confirmed in split-brain patients, but a deeper exploration in this domain also revealed an unexpected result: as reviewed for the first time by Gazzaniga in 1975, the right disconnected hemisphere of split-brain patients can process verbal stimuli "without awareness". In particular, when a word was flashed in the left visual field of a split-brain patient, the patient was unable to read the word, referring not having seen the stimulus. However, when asked to retrieve an object from a series of objects placed out of view by using the left hand (directly controlled by the right "speechless" hemisphere), the patient was able to select

the appropriate object, corresponding to the word seen by the right hemisphere. This evidence suggested for the first time that the right hemisphere can, to some extent, process linguistic information.

Besides the well-known left-/right-hemispheric dominance for linguistic/spatial abilities, a further dichotomy was proposed by Corballis (1995) as regards visual abilities and attentional resources. According to this perspective, the two cerebral hemispheres control two “visual systems”, each with its perceptual and attentional subsystems: a voluntary “spotlight”, location-based attentional system, integrated interhemispherically by means of subcortical *nuclei* (such as the pulvinar), and an automatic, object-based attentional system, hemisphere-specific and based on a fine-gradient cortical analysis. Corballis reviewed a number of evidence in support of this distinction that could be referred to the well-known distinction between the “what and where” routes of the visual system: the subcortical network would be responsible for position and movement analyses, and it would be shared by the two hemispheres, so much so that split-brain patients would be able to compare the position of two visual stimuli simultaneously presented in both visual fields. On the other hand, the cortical network would be responsible for shape, color, and form analyses, and it would be separated in split-brain patients, who would not be able to compare these attributes when simultaneously presented in both visual fields. The author concluded that the what (cortical) system is not integrated across the hemispheres and that it enables two relatively independent attentional systems in the divided brain.

Concerning the relationship between attentional processes and the auditory system, Hugdahl (2003) reviewed evidence according to which callosal fibers play a central role in orienting the attentional resources: the author claimed that the CC is not only an automatic route for the exchange of sensory information between the cerebral hemispheres but it also allows for the dynamic interhemispheric interaction due to both bottom-up and top-down sensory processing. The paradigm most exploited to investigate cerebral asymmetries in the auditory modality is the

dichotic listening task, in which two different auditory percepts (often syllables) are simultaneously presented in the two ears. By using this paradigm, a Right Ear Advantage (REA) effect has been shown in healthy listeners, and this effect has been explained by referring to the predominance of the contralateral versus the ipsilateral auditory pathway (see Fig. 2) and to the left-hemispheric superiority for language processing. Hugdahl (2003) reviewed the evidence according to which the REA effect could be reversed by asking participants to explicitly pay attention to the left ear. The author described results showing that the callosal projections could modulate this asymmetry, and thus in case of callosotomy, a left ear extinction appears, due to the absence of interhemispheric auditory exchange. Finally, the author reported a significant correlation between left ear performance and callosal size, specifically referring to the posterior portion of the CC, containing the auditory fibers.

Concluding, as suggested by Gazzaniga (2000), the CC is possibly one of the bases for the development of the complexity in our brain, in the sense that it allows for the genesis of specialized neural circuits in the brain, separately in each hemisphere. This process would have evolved by addressing extant cortical areas at reorganizing in novel ways, while preserving existing functions, and avoiding redundant systems. Despite these interhemispheric differences, however, we always experience a totally integrated sense of presence.

Conclusion

The resection of callosal fibers is a neurosurgical treatment of epilepsy and other brain pathologies which has mostly been abandoned today, thanks to the development of more efficient pharmacological therapies than those available in the past decades. The evidence collected with split-brain patients, however, allowed neuroscientists to discover many details about the integrative function of the nervous system. Despite the rareness of such treatment, split-brain patients still constitute a unique opportunity to test some hypotheses

Split-Brain Patients,

Fig. 2 Schematic representation of the direct contralateral projections of the human sensory systems (only visual and auditory pathways are represented, but contralateral projections also involve tactile, proprioceptive, and olfactory systems). *Dashed lines* represent the indirect callosal projections to the hemisphere ipsilateral to the stimulus

about hemispheric cooperation/imbalance. The literature on split-brain patients has narrowed and narrowed in the new millennium, but the few surviving split-brain patients still constitute a very interesting research sample for neuroscientists. Besides the evidence collected in decades in the USA (mainly in California, Connecticut, Massachusetts, New Hampshire, Ohio), a limited number of split-brain patients are still being tested in Italy, both from a cognitive and a neuropsychological point of view (see Prete et al. 2015) and from a morphological and functional point of view (see Polonara et al. 2015). These recent studies are even revealing novel perspectives on hemispheric lateralization, for instance, in emotion processing (Prete et al. 2015), as well as an innovative point of view about the functional role of callosal projections, which seem to be constituted not only by white matter but also seem to be the place of neuronal activation (Polonara et al. 2015). To conclude, despite the exceptionality of such a neurological condition, neither sophisticated behavioral paradigms nor neuroimaging techniques can fully replace the testing of the two disconnected cerebral hemispheres in split-brain patients (see Doron and Gazzaniga 2008).

Spontaneous Abortion and Maternal-Fetal Conflict

Jennifer Kotler

Harvard University, Boston, MA, USA

Synonyms

[Miscarriage](#)

Definition

Unexpected loss of a fetus before the 20th week of gestation.

Introduction

Evolutionary conflict occurs when natural selection acts in opposing directions on different genes involved in an interaction (Burt and Trivers 2008). Conflict can be found at all levels of organization, from conflict between species, to conflict between individuals within a species, to conflict within an individual itself. Most of these forms of conflict revolve around competition for resources and

differences in optimal resource allocation among individuals. Between genetic relatives, what is beneficial to one relative may not be beneficial, and may even be detrimental, to another. This situation occurs when there is an unequal probability that genes from one individual will be shared with another. For example, if a mother invests abundant resources in one embryo, it benefits both that embryo and, due to shared genes, the mother herself; however it will detract from the mother's ability to invest in other offspring. From the maternal perspective, she shares half her genes with each of her children, so she benefits optimally from maximizing her reproductive output. However, from the perspective of any one child, there is a lower probability that a gene found in that child's genome will be present in other siblings (although there is a 50 % probability that a maternal gene found in one sibling will be found in the other, the sibs may not be paternally related, thereby reducing their probability of genetic similarity) (Trivers 1974). Therefore there is an unequal benefit for the child relative to the mother when she allocates resources to any one child versus conserving resources for other potential offspring. These situations produce what is known as maternal-offspring conflict.

One of the earliest opportunities for maternal-offspring conflict arises when the mother physiologically “decides” whether or not to carry the child. While it is often in the best interest of genes found in the fetus to be carried to term, this comes at the cost of reducing the mother's future reproductive resources. This creates a “conflict zone,” whereby it might benefit the mother to abort this fetus in the interest of conserving her resources for future reproductive episodes.

Spontaneous Abortion in Other Mammals

Many mammals exhibit spontaneous abortion when the likelihood of infanticide is high. For example, a phenomenon known as the Bruce effect has been demonstrated in several rodent species, both in the lab and in the wild (Bruce 1960; Marashi and Rüllicke 2012). The Bruce

effect describes a striking result: recently impregnated females will undergo spontaneous abortion in the presence of a strange male. While this has been most extensively studied in rodents, a study conducted on wild geladas showed that spontaneous abortions occurred in 80 % of pregnancies when a new dominant male took over (Roberts et al. 2012). This is in line with what we would expect given that gelada males employ infanticide quite readily as a reproductive strategy, with almost 60 % of infant deaths occurring upon male replacement (Beehner and Bergman 2008). Furthermore, data on inter-birth intervals (IBIs) over time indicate that females who terminated a pregnancy had a comparable average IBI to the overall population, both of which were significantly shorter than the IBIs of females whose infant was killed by infanticide (Roberts et al. 2012). This provides further support to our understanding of spontaneous abortion as an adaptive strategy that boosts reproductive output of females.

Early Decision Making

Pregnancy is a long, expensive process. It would be extremely costly for a mother to carry an unfit embryo to term if the chances of survival and reproductive success of that offspring will be low after birth. However, there is a maternal expenditure of resources already committed to the pregnancy at the time of miscarriage; therefore any adaptive miscarriage is likely to occur as early in development as possible (Haig 1993). In humans, about 20 % of conceptions result in miscarriage before the first expected menstrual period (Ellish et al. 1996). Up to 83 % of first-trimester spontaneous abortions have been found to have chromosomal abnormalities (Strom et al. 1992), supporting our understanding of early-term miscarriage as an evolved “quality control” strategy (Haig 1993).

Fetal Response

The fetus has evolved certain defenses in response to this maternal pressure. In the case of humans,

the fetus has taken over partial control of its own fate by way of hormonal control. Before implantation human embryos already begin to secrete human chorionic gonadotropin (hCG). By the time of implantation, placental secretion of hCG into the maternal blood stream has appropriated maternal pituitary control. This prevents early regression of the corpus luteum (CL), without which an early-stage human pregnancy will miscarry (Haig 1993). Placental hCG also stimulates progesterone production, which allows the pregnancy to go to term beyond the eighth week even if the CL is removed. In this way the human fetus attempts to take control of its own fate, to the potential detriment of the mom (Haig 1993).

Conclusion

Genes found in both the mother and the fetus would benefit from increased investment in healthy sibs as opposed to maternal investment in a child unlikely to survive and reproduce. However, there is a zone of conflict in which it would be in the mom’s best interest to abort, but in baby’s best interest to be born. Both individuals have evolved mechanisms to respond to the pressures brought on by this discrepancy.

Spontaneous Language

W. Garrett Mitchener

College of Charleston, Charleston, SC, USA

Synonyms

Creolization; Grammaticalization; Language acquisition; Origin of language

Definition

Spontaneous language is the phenomenon in which all or part of a language is constructed based on innate assumptions combined with input from an environment that underspecifies the language. Input signals may be the product of a language or have a less formal source. The resulting language is consistent with the input, though it may not exactly reflect the process by which the input was generated.

Introduction

Natural human language is a complex phenomenon, with individual and communal components.

It consists of highly structured signals with rich semantics, transmitted through vocalizations, facial expressions, and manual gestures. Normal individuals each have a body of knowledge about their native language called I-language. At the community level, an E-language is the amalgam of the I-languages of all individuals and may not exactly match any individual's I-language.

I-languages are constructed instinctively and spontaneously by children as they acquire their native language, based on innate assumptions and primary linguistic data (PLD). Normally drawn from an E-language, PLD consists of gestures, utterances, and the contexts in which they are experienced. The innate assumptions, called universal grammar (UG), limit natively acquired languages to a learnable subset of all mathematically possible languages. Consequently, children receiving PLD from the same environment acquire similar I-languages, which in turn perpetuates the E-language.

The exact composition of UG is uncertain. The term UG is often associated with the principles-and-parameters (P&P) system of generative syntax and a nativist model of acquisition, which posits extensive innate knowledge of specific grammatical rules (Lightfoot 1999). An alternative is to suppose that only the most basic rules are innate and others are acquired as compound templates (Tomasello 2005; Jackendoff 2002).

The native language acquisition process in a child's brain is based on inference from experience and is not programmable. That is, if an adult explains a grammatical rule to a young child, the child cannot incorporate it into his or her language immediately the way an adult learning a second language might. Rather, the child must find evidence for the rule in the PLD and incorporate it instinctively.

There are circumstances other than routine native language acquisition under which an I- or E-language spontaneously forms. Section 2 describes language change and diversification, in which new languages emerge from the PLD of existing languages. Section 3 describes creolization, in which children construct a full language from highly impoverished PLD. The biological origin of language is discussed in section

4. Iterated learning experiments, in which human subjects or agents in a computer simulations must construct a communication system from scratch, have become a popular tool for studying language origins. These are discussed in section 5.

Language Change and Diversification

E-languages naturally have a spontaneous component (Labov 1994). Some signals and meanings drop out of use. New ones are continually invented and added to the cultural environment. Some of these innovations become widespread and others do not. The collective decision to adopt or abandon a signal or meaning depends on many social factors, such as the extent to which the community or a subcommunity associates some favored status with the signal or meaning. The sex, status, and friendship networks of those who initiate an innovation are important factors in its spread. In addition to the lexicon, grammar is subject to natural, spontaneous changes. The accumulation of such changes can transform a language drastically. For example, Old English as spoken prior to the twelfth century must be learned as a foreign language by native speakers of Modern English despite the unbroken chain of acquisition.

Language change can lead to diversification. For example, the Romance languages, including Italian, French, Spanish, and others, developed from regional dialects of Latin that diverged over centuries.

Language changes can sometimes be attributed to a specific nonlinguistic event, especially contact with another culture (Trask 1996). English borrowed many words from French during the Norman conquest in the eleventh century. However, some changes appear to happen spontaneously, in the sense that there is no nonlinguistic driving force. For example, the sound systems of languages are in constant flux. Vowel shifts, such as those that occurred over centuries in English and Greek, seem to arise directly from speech and language acquisition. More complex changes called reanalysis and grammaticalization affect morphology and syntax. These arise from inherent ambiguities in language. For example, the

definite article “the” in Modern English arose from an Old English demonstrative, and the indefinite article “a/an” came from a word meaning “one.”

Creolization

A pidgin is an artificial language constructed by societies in contact for which no natural language suffices for communication. Most pidgins originated during the colonial era as a tool for trade, or by culturally mixed slave communities. They generally lack agreement morphology and complex syntax such as embedded clauses. Their vocabulary is minimal and utilitarian. A creole is a natural language that appears to have been derived by simplifying the phonology and lexicon of another language and imposing a simplified but fully expressive grammar with recursion, minimal inflectional morphology, and regular derivational morphology. Creoles arise when children extract PLD from a pidgin, and spontaneously complete it to a natural language, a process called creolization (Bickerton 2008), though some linguists disagree with this characterization. Creole grammars are generally more similar to each other than to those of their parent languages, which suggests that this kind of grammar might reflect some default state of the language acquisition process.

Sign languages can also form via creolization. If isolated from other signers, deaf children develop an ad hoc gesture system called home sign for communicating with their hearing family members. When isolated deaf people form a community, they share their home signs. Deaf children entering such communities treat these gestures as PLD and develop it into a complete sign language analogous to a spoken creole. A well-documented case of spontaneous sign language formation occurred when the first school for the deaf opened in Nicaragua (Senghas and Coppola 2001).

Biological Origin of the Language Faculty

It is generally accepted by the scientific community that a combination of genetic mutations and

natural selection led to the spontaneous evolution of the language faculty among hominins (Tallerman and Gibson 2012; Hauser et al. 2002).

The human language faculty is distinct from the communication abilities of the other great apes. Although chimpanzees and gorillas have been successfully taught to use signs and other forms of communication, the process is laborious, and the subject animals never develop human-like syntax and fluency. The human language faculty must have evolved sometime after hominins and chimpanzees diverged 4–8 million years ago.

Little physical evidence related to the biological history of human language is available, and it is indirect and difficult to interpret. The oldest known artifacts with writing are only a few thousand years old, which is too recent to be informative. Fossils yield only indirect information about brain and vocal tract anatomy. There is physical evidence of artifact use and cultural practices of hominins, but the extent to which these behaviors may reliably serve as proxies for language ability is uncertain. Genetic evidence is also elusive. The genes involved in language must have experienced mutations and selective sweeps since the divergence of chimpanzees and hominins. There are statistical tests for identifying genes that have experienced such events; however, they are controversial and of limited inferential power (That said, the regulatory gene *FOXP2* has been identified as affecting language. Its function is not well understood.) Consequently, investigations into the biological history of human language consist primarily of identification of general principles, formulation of plausible scenarios, testing of hypotheses via simulation, and informed speculation.

Neanderthals probably had some form of language. They were genetically similar enough to modern humans to interbreed, and fossil evidence suggests that the Neanderthal vocal tract was similar to that of modern humans. That would place the origin of language prior to the divergence of the two species about 500,000 years ago.

There are two hypotheses about the timescale of the origin of language. Originating from the observation that the language faculty is difficult to divide into smaller features that could have plausibly been selected for independently, the saltational or sudden hypothesis is that the

transition from a prelinguistic ancestor species happened relatively rapidly and is possibly due to a single evolutionary event. However, organisms normally evolve new features by accumulating modifications to existing features, and it is unlikely that one mutation would construct a complete language faculty from essentially nothing. A more biologically plausible gradual hypothesis is that the language faculty arose in several steps, accompanied by a sequence of protolanguages.

A plausible gradual scenario is as follows. The ability to observe and mimic complex sequences of gestures improved. Societies became large and complex. Cognitive functions that originally served to keep track of personalities, intentions, dominance, and friendships were exapted to form a theory of mind. Hominin intelligence was increased by extending the period of brain growth after birth, resulting in a long childhood and more opportunities for learning. Communal activities such as rearing children, producing tools, acquiring food, and finding mates were facilitated by communication. A protolanguage faculty formed and further mutations improved it. A theoretical challenge is that social structure, hunting, foraging, child-rearing, culture, and E-languages all had to change along with the language faculty. Improvements in one of these areas became possible only after improvements in some of the others.

The composition of protolanguage is lost to history. It is possible that early child language reflects protolanguage, in which case it would have consisted largely of short phrases of one to three protowords and gestures primarily expressing requests, general intentions, and attempts to bring something to another individual's attention. Much of the meaning would have to be extracted from context and assumptions shared between speaker and hearer. The recursive nature of syntax, in which entire sentences can be nested within a sentence, is generally thought to be a recent addition to the language faculty.

Iterated Learning Experiments

In light of the limited data, investigations into the origins of language often include simulations.

A popular paradigm is iterated learning (Lyon et al. 2007, Chap. 13). Subjects (humans or computer programs) are placed in a scenario where communication is required, but no natural language is available. Subjects must produce signals and develop a mapping from signals to meanings. Repeatedly, another generation of subjects replaces all or part of the existing generation. Each generation receives some information about how the previous generation used signals, and are asked to perform the same kind of task. The communication system evolves in a cultural sense, and its trajectory reveals something about how a natural or artificial learning process interacts with communication in use. Rules for forming structured signals can form spontaneously.

Iterated learning experiments have been performed on these topics, among others: the acquisition, persistence, and loss of irregular versus regular morphology; how structure in signals reflects structure in meanings; the effect of an expectation by the learner that signals have structure; differences between adult learners and child learners; and the formation and perception of signal-mediated social status. Uncertainty remains about how well these experiments reflect natural language formation.

Conclusion

Human language has many spontaneous aspects. Children learn native I-languages instinctively. Adults introduce variation into communal E-languages. This combination of use and learning causes languages to change and diverge. New creole languages can be formed from highly impoverished primary linguistic data. The language faculty is thought to have evolved in hominins prior to the divergence of modern humans and Neanderthals, likely due to many mutations that improved intelligence, learning, motor control, and social structure. Humans and automated learning processes can construct sophisticated dynamic communication systems via iterated learning.

Spontaneous Recovery

Androulla Ioannou and Xenia Anastassiou-Hadjicharalambous
University of Nicosia, Nicosia, Cyprus

Definition

The recovery of a habituated response.

Introduction

Spontaneous recovery is a phenomenon encountered within non-associative learning processes.

The Process of Spontaneous Recovery

In a series of experiments undergone by Rankin and Broster (1992) on the nematode *Caenorhabditis elegans*, mechanical stimuli were delivered at four interstimulus intervals (2, 10, 30, and 60 s) in order to investigate the effect of interstimulus intervals in the development and maintenance of habituation. Results indicated that recovery from habituation was dependent on some factors. One of these factors is the length of interstimulus intervals; it was observed that recovery from habituation was faster when short interstimulus intervals were applied rather than longer interstimulus intervals. That is, long-term habituation prevents recovery. Also, the rate of recovery varied according to which response level each subject exhibited on the habituation curve. The recovery of animals on the lowest response level appeared to be determined by interstimulus interval and not by the further addition of stimuli. Interstimulus interval recovery rates did not differ even though the number of stimuli the worms received was significantly bigger (60 vs. 10) in the second group. In short what was evident is that

the frequency of stimulation during habituation training was the one to determine the rate of spontaneous recovery.

Moreover, Rankin et al. (2009) upon revisiting the characteristics of habituation, originally described by Thompson and Spencer (1966), revised a point concerning spontaneous recovery. It is described in the characteristics that when a sequence of stimulus presentations is interrupted, the object at hand will return to its earlier stage, and the behavior will recover over time. Rankin and colleagues (2009) revised this characteristic by adding that sometimes the response recovers completely, but sometimes it recovers only partially depending on the time frame that recovery was examined.

Further, when stimulus presentations and spontaneous recoveries are given repeatedly, the phenomenon of *potentiation of habituation* is observed. Here, the decrement in response that follows spontaneous recovery (i.e., habituation) becomes gradually more rapid with each application of spontaneous recovery. Moreover, the process of spontaneous recovery can be disrupted with the presentation of a new, strong stimulus, that is, sensitization.

Lastly, it is crucial to note the importance of spontaneous recovery; it is the second way, with stimulus discrimination being the first way, to distinguish sensory adaptation and fatigue from habituation. With regards to learning, this process demonstrates that even though a response might disappear, it does not necessarily mean that it has been withdrawn from memory and that it will never reoccur.

Conclusion

Experiments on the lowest living forms illustrate the phenomenon of spontaneous recovery and those indicate that spontaneous recovery is highly determined by the frequency of stimulus presentation. These experiments provided a special insight on the underlying processes of habituation.

Spousal Abuse and Homicide: Byproduct Theory (Daly and Wilson)

Leah C. Teter and Joseph A. Camilleri
Westfield State University, Westfield, MA, USA

Synonyms

[Intimate Partner Violence](#); [Intimate Partner Homicide](#)

Though most homicides are perpetrated by men against other men, women are disproportionately the victims of spousal homicide. Globally, 39% of

all homicides of women are by an intimate partner, whereas 6.28% of all homicides of men are by an intimate partner (Stöckl et al. 2013). Daly and Wilson proposed that uxoricide (i.e., killing of female spouse) is a byproduct of male sexual proprietariness. Male sexual proprietariness is a tendency for men to believe they own or are entitled to their intimate partner. Such beliefs would have been an adaptive response to competition with rival males. Men can increase their reproductive success through mate number, which creates a high degree of competition between men for access to mates. Men who were able to limit their intimate partner's mating opportunities with rivals would have been more successful than men who did not. Having a partner who engages in extra-pair mating introduces a cost – investing resources and time in raising offspring who are not genetically related (known as cuckoldry risk). Daly and Wilson suggest that intimate partner violence may function by limiting a partner's extra-pair opportunities through coercive control to reduce the risk of cuckoldry and that uxoricide is a byproduct of such actions.

A trait is considered to be a byproduct if it is not-adaptive because it does not solve any reproductive or survival problems (Buss et al. 1998). Daly and Wilson (1988) argue that in order for spousal homicide to be an adaptation, it requires a clear reproductive or sexual benefit, but if a husband kills his wife, it prevents any future reproductive success and presents additional costs such as retribution from the victim's family, loss of caregiver to any current offspring, and gaining a reputation as a murderer which hinders the acquisition of new mates. They therefore suggest that spousal homicide is not an adaptation, but a byproduct of male sexual proprietariness because many incidents of uxoricide occur in the context of sexual jealousy or loss of a partner to a rival (c.f. chapter "[Spousal Abuse and Homicide: Evolved Homicide Module Theory \(Buss\) \[Spousal Homicide\]](#)").

Daly and Wilson's hypothesis of homicide as an evolutionary byproduct explains many of the identified risk factors and demographics associated with patterns of spousal homicide rates. It explains that younger women are at higher risk

of being victims of uxoricide because there is greater competition among men for partners with higher reproductive value. Estrangement is also a risk factor because it results in losing a partner to a rival, creating a higher degree of conflict. The byproduct hypothesis also explains socio-economic status as a correlate of spousal homicide because men of lower socio-economic status may be more prone to losing a partner to a higher-status male. The prevalence of ethnic minorities as perpetrators is not explained by evolutionary principles, but Campbell et al. (2007) suggest that this pattern could be due to higher rates of unemployment among ethnic minorities in the USA. Using coercive tactics may mitigate these various conditions that increase the risk of losing a partner to a rival, but they also risk more severe actions, including homicide.

Conclusion

Spousal homicide has been hypothesized to be a by-product of male sexual proprietariness, when spousal abuse may function by limiting men's sexual partner's mating option.

Spousal Abuse and Homicide: Evolved Homicide Module Theory (Buss) [Spousal Homicide]

Ana M. Reinke and Joseph A. Camilleri
Westfield State University, Westfield, MA, USA

Synonyms

[Intimate partner violence](#); [Partner abuse](#)

Definition

Spousal abuse is when someone use physical violence, sexual violence, stalking, psychological aggression, or coercive acts toward a current or former intimate partner.

Introduction

Intimate partner violence (also called partner abuse) is when someone uses physical violence, sexual violence, stalking, psychological aggression, or coercive acts toward a current or former intimate partner (Centers for Disease Control and Prevention 2018). Intimate partner violence is often habitual and can escalate, resulting in serious injury or homicide (Focht 2018). *Evolved Homicide Module Theory* (also referred to as ► [“Homicide Adaptation Theory”](#), see entry) provides an explanation for why intimate partner violence may result in homicide by suggesting that homicide evolved through natural selection by ultimately providing fitness benefits while minimizing costs (Duntley and Buss 2011).

An adaptation is any change in the structure or function of a phenotype through natural selection by better equipping the organism to survive and reproduce. Generally, homicide may be an adaptation because it functions by resolving conflict. For example, homicide may increase fitness by preventing one's own premature death, acquiring resources, reducing the number of rivals for

oneself and one's children, avoiding investing in stepchildren, and developing an aggressive reputation to prevent challenges from rivals (Duntley and Buss 2011). Spousal homicide may therefore be functional. Buss (2006) suggested that in addition to losing a partner, cuckoldry provides a major cost, and such a cost is compounded by a rival's reproductive gains. Under these circumstances, it is theorized that killing a spouse reduces the fitness of rivals while maintaining a reputation that one is not to be exploited. Supporting this hypothesis are the number of intimate partner homicides that are preceded by sexual jealousy or intimate partners leaving the relationship (Buss 2006; Shackelford et al. 2003). There is also some suggestion that women may have evolved anti-homicide defenses, but these ideas have not been fully explored or tested.

A potential challenge to the spousal homicide as an adaptation hypothesis are the steep costs associated with such actions, including losing a reproductive partner, removal of a caregiver to one's offspring, gaining a reputation as a murderer, and familial retribution.

Although men account for most spousal homicides, in some areas women account for almost as many spousal homicides (Wilson and Daly 1992). The motivation behind women's killing of men are not the same as men's – most instances of women's spousal murder is in self-defense from an abusive partner (Wilson and Daly 1992). Daly and Wilson suggested that spousal homicide is a byproduct of male sexual proprietariness, which is when aggressive autonomy-limiting actions are used to prevent cuckoldry. Spousal homicides are therefore nonadaptive, extreme manifestations of men's coercive control (see ► “Spousal Abuse and Homicide: Byproduct Theory (Daly and Wilson)” entry). Women's killing of men seems to be in response to men's aggression toward them. Very little theoretical or empirical work, however, has considered these cases.

Conclusion

Spousal homicide has been hypothesized to function as an adaptation to reduce reproductive success of rivals while maintaining one's status of not

being a cuckold. It is not yet clear whether spousal homicide evolved as an adaptation, or is a by-product of male sexual proprietariness.

Stages of Development

Benjamin Campbell

Department of Anthropology, University of
Wisconsin-Milwaukee, Milwaukee, WI, USA

Synonyms

[Developmental stage](#); [Life cycle](#)

Definition

Phases that all individuals pass through in a normal lifetime.

Introduction

The fact that humans progress through a set of distinctive stages over the life course is readily observed in others and subjectively experienced. However, the number and definition of those stages have shifted over the course of the Western tradition from 3 to as many as 12 distinct stages, making it clear that the classification of life stages is in part a cultural representation (Mintz 1993). Erik Erikson (Erikson and Erikson 1987) proposed seven life stages, including infancy, toddlerhood, middle childhood, adolescence, and young, middle, and old age, based on psychosocial identity, representing the most widely known cultural model of the life course for the late twenty-first century.

Yet, Erikson leaves out fetal development, a stage only visible to the casual observer from the outside, emphasizing Erikson's life stages as based on subjective experience. But increasingly the use of noninvasive techniques such as ultrasound imaging has made prenatal development accessible to observation. In fact, a more sophisticated understanding of the biology of development has given us a picture of the species-specific processes underlying life stages that go beyond well-defined social roles and individual psychology.

This entry on life stages outlines phases of the human life course based on overlapping biological, psychological, and social elements. Importantly, the advent of brain imaging techniques means that in addition to physical traits used to define life stages, we can add changes in the brain to the developmental picture. Given that the brain is both part of the body and the locus of behavior, this brings us closer to an integrated biopsychosocial model. Steroid hormones provide an additional link between development, brain, and behavior.

Below I list eight different life stages, including fetus, infancy, early and middle childhood, adolescence, and young, middle, and old age. I describe key aspects of their biological underpinnings, and brain correlates along with some psychological components and social interaction. Because the biopsychosocial model implicit in my discussion comes most clearly into evolutionary perspective with comparison to our closest relatives the great apes, I also compare human life history with the relevant findings among chimpanzees the species for whom we have the most information.

Prenatal Stage. Fetal development is traditionally subdivided into three phases, or trimesters, each characterized by different elements of prenatal growth and/or development. The first trimester is defined by the development of a complete organism from the initial undifferentiated ball of cells. The second trimester is defined by the development of organ systems. The fetus is now potentially viable outside the womb. The third trimester is defined by growth of the fetus. It is at this point that the brain becomes a large part of the fetus energy demands on the mother.

Though difficult to observe directly, fetal development is important because being first it has the capacity to effect all other life stages, through prenatal programming, i.e., setting the fundamental conditions for all subsequent development. Hormones are one important such mechanism. Much of the focus has been on the hypothalamic pituitary axis (HPA) which mediates the effects of prenatal stress on cortisol reactivity during infancy and later in life (Howland et al. 2017). Androgens also play a role. For instance, females with congenital adrenal

hyperplasia which exposed them to high level of DHEA, a weak androgen, in utero show increased aggression and activity levels. Whether such results can be extended to the larger populations is unclear (Hines et al. 2015). Separately, infants born premature or at very low birth weights show reduction in executive function (van Houdt et al. 2019), reflecting disrupted development of the prefrontal cortex with implications for lifelong intelligence and social behavior.

Infancy. The infant stage extends from birth to weaning and is characterized by rapid but declining somatic growth (Bogin 1999). Exclusive breastfeeding is sufficient for the infant's energetic needs for the first 6 months after which the diet must be supplemented with supplementary foods. In subsistence societies the average age of weaning is about 3 years. Hence 3 years marks a milestone in the degree of direct comforting nutritional physical contact with the mother and signals increasing interaction with others. During this stage the brain is growing rapidly in size, and the limbic system is developing.

Mother-infant interaction is central to infancy and leads to attachment as defined by John Bowlby (1982). The nature of such attachment shapes the internal model the infant develops of itself with important implications for all personal relationships formed after infancy. Secure attachment develops when an infant feels love and positive regard and avoidant when it feels unloved and rejected, and resistant attachment is based on the infant feeling angry and confused.

One important element of maternal behavior is a high pitched emotional voice referred to as motherese. Motherese appears to peak at around 7 months, just when the infant can be put down for longer periods of time. Variation in receptive and expressive language is related to the size of the amygdala suggesting that the infant's early experience of security with the mother has an important effect on the development of basic cognitive skills.

Infancy is also defined by the rapid development of two defining human skills, bipedal walking and spoken language. Walking generally starts around 9–12 months, developing from crawling. Language itself develops starting around 1 year,

though it follows a long period of vocalization. Once initiated early language development progresses at a dizzying rate, as any parent can attest.

Childhood. Childhood is defined as the period between weaning and the onset of puberty, thus stretching from the age of 3 to 12 years. However, such a long period includes at least two distinct phases: early childhood defined as age 3–6 years and middle childhood from 6 to 12 years. Some authors separate late childhood, defined as between the ages of 10 to 12 as a third stage.

Early childhood is associated with continued growth of the brain with volume reaching 95% of adult values by age 7. This is also a period of increased synaptogenesis with increased energetic demands. Brain glucose utilization peaks around 5 years (Kuzawa et al. 2014). Somatic growth is slow and linear (Bogin 1999), suggesting a possible trade-off with brain growth. There is a rapid development of motor skills.
